ETON, in *Geography*, a large village in the hundred of Stoke, and county of Buckingham, England, is noted for its great public ſeminary, or college, in which many eminent ſtateſmen, authors, military heroes, &c. have received their ſcholaſtic education. This college was originally founded by king Henry the Sixth, in the year 1440, for a provoſt, ten prieſts, four clerks, ſix choriſters, twenty-five poor grammar-ſcholars, and twenty-five poor men. The firſt provoſt was Henry Sever, who was ſucceeded by William Waynfleet, founder of Magdalen college, Oxford. This foundation was particularly excepted in the act for the diſſolution of colleges and chantries, in the time of Edward VI. Its eſtabliſhment, however, has been in ſome degree altered, and now conſiſts of a provoſt, ſeven fellows, two ſchoolmaſters, two conducts, ſeven clerks, ſeventy ſcholars, and ten choriſters, beſides inferior officers and ſervants. The annual election of ſcholars to King's college, Cambridge, founded alſo by Henry VI. takes place about the end of July, or the beginning of Auguſt, when twelve of the ſenior boys are put on the roll to ſucceed in this college as vacancies occur. The average number of vacancies are about nine in two years: at nineteen years of age the ſcholars are ſuperannuated. Eton college alſo ſends two ſcholars to Merton college, Oxford, where they are denominated poſtmaſters. It has a few exhibitions, of twenty-one guineas each, for its ſuperannuated ſcholars, towards whoſe aſſiſtance Mr. Chamberlayne, a late fellow, has bequeathed an eſtate of 80*l. per annum*, after the death of his widow. The ſcholars elected to King's college ſucceed to fellowſhips at three years' ſtanding. The independent ſcholars at Eton, commonly called Oppidans, are very numerous; the average number having been for ſeveral years paſt from 300 to 350: when Dr. Bernard was maſter, under whom the ſchool particularly flouriſhed, the number at one time exceeded 520. Among the many diſtinguiſhed perſons who received their education here we find the names of biſhop Fleetwood, biſhop Pearſon, John Hales, Dr. Stanhope, ſir Robert Walpole, Horace Walpole, Oughtred the mathematician, Boyle the philoſopher, Waller, Gray, Weſt, the late earls Camden and Chatham, and the late learned Jacob Bryant; with many other eminent literary and public characters of the preſent day.

An ancient cuſtom, appertaining to this college, called the "Montem," or "Ad montem," muſt not be paſſed unnoticed. This is a proceſſion of all the ſcholars, &c., made every third year on Whit-Tueſday, to a tumulus, which has acquired the name of *Salt-hill*, by which alſo the neighbouring inns have been long known. The chief object of this ceremony is to collect money for *ſalt*, as the phraſe is, from all perſons preſent, even from paſſengers travelling the road. The collecting ſcholars are called ſalt-bearers, and are dreſſed in rich ſilk habits. This ceremony has been frequently honoured with the preſence of the king and royal family, whoſe liberal contributions, added to thoſe of the nobility and gentry educated at Eton, who purpoſely attend this meeting, have ſo far augmented the collection, that it has been known to exceed 800*l.* The ſum ſo collected is given to the ſenior ſcholar who is going to Cambridge for his ſupport at the univerſity. It would perhaps be a vain endeavour to trace the origin of all the circumſtances of this ſingular cuſtom, particularly that of collecting money for *ſalt*, which has been in uſe for time immemorial. The proceſſion itſelf ſeems to have been coeval with the foundation of the college, and it has been conjectured, with much probability, that it was that of the bairn or boy biſhop. It is ſo aſſerted in a note among the MS. collections bequeathed to the Britiſh Muſeum by Mr. Cole, who was of Eton and King's college: but whence he procured this information, which, if correct, might be deciſive, does not appear. The cuſtom of hunting a ram by the Eton ſcholars on Saturday in the election week, ſuppoſed to have been an ancient tenure, was aboliſhed by the late provoſt Dr. Cooke.

Eton college conſiſts of two quadrangles: in the firſt are the ſchool, the chapel, and lodgings for the maſters and ſcholars. The other is occupied by the library, the provoſt's lodgings, and the apartments of the fellows. The chapel, as far as relates to its external appearance, is a very handſome ſtructure; the inſide has none of that ornamental architecture ſo much admired in King's college chapel at Cambridge, to which this has ſometimes been compared, but is quite plain, and has been much diſfigured by ſome injudicious alterations, made in the beginning of the laſt century, when ſeveral of the monuments were removed, and others concealed behind the wainſcot then placed at the eaſt end. The whole length of the chapel is 175 feet, including the ante-chapel, which is 62 feet long. Among the eminent perſons who are buried in this chapel, are Richard, lord Grey of Wilton, henchman to king Henry VIII.; John Longland, biſhop of Lincoln, confeſſor to that monarch; ſir Henry Saville, the learned warden of Merton, and provoſt of this college, who founded the Savilian profeſſorſhips of aſtronomy and geometry at Oxford; ſir Henry Wotton, an eminent ambaſſador and ſtateſman, who was alſo provoſt of Eton; Francis Rowſe, a diſtinguiſhed writer among the puritans, and one of the lords of Cromwell's upper-houſe, who died while provoſt of Eton in 1658; Dr. Alleſtree, alſo provoſt, an eminent royaliſt, who built the new or upper ſchool, with the cloiſters beneath, at the expence of 1500*l.*, and died in 1680; and Nathaniel Ingelo, who died in 1683. The monuments of ſome of the above-mentioned perſons are not now to ſeen. Sir Henry Wotton's tomb has the following ſingular inſcription:

> "Hic jacet hujus ſententiæ primus auctor—
> Diſputandi pruritus fit eccleſiarum ſcabies"
> "Nomen alias quære."

In the ante-chapel is a ſtatue of the founder, by Bacon, erected in 1786; the ſum of 600*l.* having been bequeathed for that purpoſe by the Rev. Edward Betham, fellow of the college, who died in 1783: and a monument of the young earl of Waldegrave, who was drowned when at Eton ſchool, in 1794.

The college library contains a very large and valuable collection of books, having been from time to time enriched by munificent bequeſts.

In 1452 the college had a charter for a market on Wedneſdays, with conſiderable privileges; but it has been long diſuſed. Two fairs were granted by the charter of 1444: one for the three days following Aſh Wedneſday, the other for ſix days next after the 13th of Auguſt. There is now only one fair, held on Aſh-Wedneſday. The pariſh church of Eton, called in ancient records Eton-Gildables, having been ſuffered to fall to decay, the inhabitants are permitted to attend divine ſervice in the college chapel. The provoſt is always rector, and has archidiaconal juriſdiction within the pariſh. There is a chapel of eaſe in the village ſerved by one of the conducts of the college; it was built for the uſe of the inhabitants by William Hetherington, who had been one of the fellows, and was a very liberal benefactor to the blind and to the poor of other deſcriptions.

Eton is ſituated on the northern banks of the Thames, oppoſite to Windſor, with which it is connected by a bridge. It is 22 miles diſtant from London; conſiſts chiefly of one ſtreet; and contains 290 houſes, and 2026 inhabitants. Lyſons's Magna Britannia, vol. i. Beauties of England and Wales, vol. i.

ETORPU, one of the Kuriſkoy or Kurile iſlands, lying 30 verſts from Urup; and about 300 verſts in extent. The whole iſland is covered with lofty mountains; one of which, at the northern extremity, emits a continual ſmoke, and occaſionally flames. The ſummits of the mountains are bald, with ſteep cliffs and heaps of rubbiſh. Here are foreſts, conſiſting of the ſame trees with thoſe of the iſland

Urup. In the ſouthern half, near about the centre of the iſland, grew larch-trees, in the proximity of the ſea, but ſlender, though further inland, in the plains of the vallies, good timber trees, fit for the purpoſes of building. Here are likewiſe black bears, and in the foreſts ſables and foxes are met with. Of rats there is no ſcarcity; fiſh-otters haunt the ſtreams; and the brooks abound in fiſh. During the ſtorms that happen here, whales and large dolphins are thrown aſhore by the ſea. The ſea-otter is not ſeen here, but ſea-lions, though not of any great dimenſions. The inhabitants are hairy Kurils, who dwell together in villages. They are numbered in the capitation-tax at 92 perſons.

ETREPAGNY, or ESTREPAGNI, a ſmall town of France, in the department of the Eure, chief place of a canton in the diſtrict of Les Andélys, with a population of 1201 individuals. It is ſituated 9 miles from les Andélys, and 9 miles W. of Giſors; its canton contains 10,442 inhabitants, diſperſed in 26 communes, on a territorial extent of 140 kiliometres.

ETRIGNY, a town of France, in the department of the Saone and Loire, and diſtrict of Chalons-ſur-Saone; 3½ leagues S. of Chalons.

ETRIS, a town of Egypt; 18 miles N.W. of Cairo.

ETROEUNG, a town of France, in the department of the North, and diſtrict of Aveſnes; 1¼ league S. of Aveſnes.

ETRURIA, in *Ancient Geography*, a country of Italy, ſeparated on the weſt from Liguria by the river Macra; from Latium and Umbria on the eaſt by the Tiber; on the north-eaſt by a part of the Apennines from the country of the people called Boii and Senones; and on the ſouth-weſt waſhed by a portion of the Mediterranean ſea, called Mare Tuſcum, or Tyrrhenum, the Tyrrhenian ſea. This country was once more extenſive than the preſent Tuſcany, as it reached as far as the Tiber. The inhabitants of Etruria, who for a long time poſſeſſed a great part of Italy, were denominated Tuſci or Etruſci. (See ETRUSCI.) The principal rivers of this country were the Arnus, the Umbro, the Clanis, and the Tiber. The chief lakes were the Lacus Traſimanus, and Vulſinienſis. Among the moſt conſiderable cities we may reckon Luna, Piſæ, Luca, Pittoria, Florentia, Feſulæ, Portus Herculis, Labronis, Voluterræ, Sena Julia, Arretium, Cortona, Peruſia, Cluſium, Vetularii, &c. &c.

ETRURIA, in *Geography*, a country ſituated between the Mediterranean, the Tiber, and the Apennines; bounded on the eaſt by the dominions of the pope, on the north and north-eaſt by the kingdom of Italy, on the weſt by the republic of Lucca, and on the ſouth-weſt by the Mediterranean; about 115 miles in length, and 80 in breadth. The face of this country is beautifully varied with hills and vallies, and the ſoil which is rich and fertile produces abundance of corn, and excellent fruit, oranges, lemons, olives and grapes. The air is in ſeveral parts rendered inſalubrious by fens and moraſſes; the ſalt-pits are rich. Manna is gathered in the marſh-lands near the ſea; and the mountainous parts are rich in mines and minerals. Several medicinal ſprings have been diſcovered beſides thoſe of Piſa. Arno is the principal river; and Florence is the capital. After ſeveral revolutions, Etruria became a republic, and deriving its name from its capital, was called Florence. And in this republic the Medici family obtained by commerce the wealth and rank of princes. It was alſo denominated *Tuſcany*, which ſee; and in 1569, Coſmo I. was declared duke of Tuſcany by pope Pius V., which title was ratified by the emperor Maximilian II. in the year 1575, on condition of his enjoying and holding it as a fief of the empire. By the fifth article of the quadruple alliance, made in 1718, it was ſtipulated that, with the conſent of the Germanic body, the emperor ſhould confer it as a fief on the king of Spain's eldeſt ſon by the ſecond marriage, and that it ſhould devolve to his male deſcendants, and on their failure to the younger brother and his heirs. In 1737 the duchy of Tuſcany became annexed to the houſe of Auſtria. By the fifth article of the treaty of Luneville in 1801, the duchy of Tuſcany was ceded to the duke of Parma, and erected into a kingdom, under the name of Etruria. It has ſince been annexed to the kingdom of Italy.

ETRUSCA TERRA, in the *Materia Medica*, a kind of bole of which there are two ſpecies, the white and the red; theſe are called by many authors the *terra ſigillata alba & rubra magni ducis*, as they are brought to us ſealed with different impreſſions.

The *white Tuſcan earth* is a denſe and compact ſubſtance of a dull deadiſh white, which in drying acquires ſome degree of yellowneſs; it is of a ſmooth ſurface, and does not ſtain the fingers in handling. It is not eaſily broken, and but ſlightly adheres to the tongue, and freely melts into a ſubſtance like butter in the mouth. It makes a ſlight efferveſcence with acid menſtruums.

The *red Tuſcan earth* is a pure bole, very heavy, and of a compact texture, and of a dull browniſh red colour. It is naturally of a ſmooth ſurface, breaks eaſily between the fingers, and does not ſtain the hands; it adheres ſtrongly to the tongue, and melts freely in the mouth, and has a ſtrong aſtringent taſte, and leaves no ſandy harſhneſs between the teeth. It makes an efferveſcence with acid menſtrua. This is made up of ſmall flat cakes, and impreſſed with a ſhield bearing a ducal coronet, &c. Theſe are the characters by which both theſe earths may be known from others of the ſame colour: they are both dug in ſeveral parts of Italy, particularly in the neighbourhood of Florence: they are kept in the ſhops there, and preſcribed with ſucceſs in fevers of many kinds, and in diarrhœas, dyſenteries, and the like caſes.

ETRUSCI, ETRUSCANS, in *Ancient Geography*, a people of Italy, who inhabited that part which is now called Tuſcany; though it was formerly much more extenſive under the name of *Etruria*. The Etruſcans, in very ancient times, are ſuppoſed to have been maſters of almoſt all Italy; for the whole region called Italia by the Latins was denominated by the more ancient Greeks Tyrrhenia, according to Dionyſius Halicarnaſſenſis (Antiq. Rom. lib. i.); whence it is inferred, that it was formerly ſubject to the Tyrrhenians, or Etruſcans, and from them received that denomination. Livy and Plutarch intimate, that the ſeas, which partly ſurround Italy, *viz.* the Tyrrhenian, Ionian, and Adriatic, were anciently denominated the Etruſcan ſea; and that the Etruſcans poſſeſſed the whole large tract extending from the Alps to the ſtraits ſeparating Italy from Sicily. They built twelve cities beyond the Tiber, which were afterwards the boundary of Etruria Proper on one ſide; and they were the founders of Nola and Capua, and poſſeſſed twelve capital cities in the tract terminated by th Po and the Alps. Virgil and Silius Italicus rank Cæſena and Mantua among the cities of Etruſcan extraction; and we learn from Livy, that this ancient nation in very early times occupied the whole tract between the Alps and the Apennines. According to Pliny, Bononia, or Bologne, was anciently regarded as the principal city of Etruria; and we may obſerve, that many Etruſcan relics and fragments of antiquity have been dug up in various provinces of the kingdom of Naples, Verona, Padua, &c. as well as the duchy of Tuſcany, or the Proper Etruria. The kingdom of Latium was probably a colony of the Etruſcans; and the firſt traces of the city of Rome may poſſibly have been owing to that nation. However, in proceſs of time, the Gauls made ſeveral irruptions into Etruria, and ſeized upon that part of it which lay between the Alps and the Apennines. The firſt of theſe irruptions happened about 600 years B.C. and the laſt a little before the taking of Rome by Brennus. Several colonies of Greeks made ſettlements in the ſuperior part of Etruria; and from them it was denominated Magna Græcia. The Etruſcans were likewiſe diſpoſſeſſed of a large extent of territory by the Samnites and Ligurians, long before they ſubmitted to the Romans; ſo that at laſt they found themſelves confined within the limits of Etruria Propria, where for ſeveral ages they made a very conſiderable figure. Etruria was called by the moſt ancient Greeks Tyrſenia; but Polybius, and thoſe who lived after him, denominated this country Tyrrhenia. Tyrſenia is ſaid to be the true name, as it correſponds with that of the Lydian prince, Tyrſenus, under whoſe conduct, according to Herodotus, the Tyrſeni, or Tyrrheni, firſt made a ſettlement in Italy. Etruria was divided into twelve ſtates or dynaſties, each of which had its peculiar city. Each ſtate or tribe was governed by its own prince, called in the Etruſcan language "Lucumo," and received its denomination from the capital city. See Etruria.

The Tyrſeni, or Etruſcans, were a branch of the Pelaſgi, that migrated into Europe, according to Dionyſius Halicarnaſſenſis, not many ages after the diſperſion. Thoſe who marched by land as far as Lydia detached a colony under the conduct of Tyrſenus to Italy. This colony ſeems to have been joined by a body of Pelaſgi, previouſly ſettled in ſome of the iſlands of the Archipelago. Hence ſome have concluded that the Lydian Pelaſgi, or Etruſcans, conducted by Tyrſenus into Italy, and the firſt Pelaſgi that inhabited Greece, were the ſame people; but Dionyſius Halicarnaſſenſis makes the Tyrſenians and Pelaſgi two different nations. The Etruſcans denominated themſelves Raſeni, from their leader Raſan, or Raſen; and Tyrſenus, or Tyrſen, is ſaid to be only the name Reſen, with the ſervile letter T ſuperadded. This circumſtance ſerves to evince, not only that the Etruſcan name of the people under conſideration agreed with that of the Greeks, but likewiſe that they were both of oriental extraction. See Pelasgi.

The Etruſcans ſeem to have derived their appellation from Etruri, or Eturi, as they were anciently denominated; and that this appellation was deduced from Athuria, or Aturia, that of their parental country, may be proved from Dionyſius Halicarnaſſenſis, Strabo, and Dio. Moreover, Aturia and Aſſyria differ merely in dialect; the former being equivalent to the Chaldæan word אתוריא, and the latter to the Hebrew אשור, as may be evinced from Bochart (Phaleg. l. ii. c. 3.) and others. Since, therefore, nothing is more frequent than the permutation of A and E in oriental words, eſpecially when written in Greek letters, Atura and Etura muſt be regarded as the ſame word, and as the ancient name of Etruria. More eſpecially if we conſider that Reſen was a city of Aturia or Aſſyria, whence, probably, the leaders of the Etrurian or Etruſcan colony were denominated Raſeni, or Reſeni; and that, from the ſacred hiſtorian, we may conclude Aſhur to have been the brother of Lud, or great anceſtor of the Lydians. The term Tuſci, or Thuſci, is of a later date, and ſeems to have been given to the Etruſcans by the Greeks. The ſacrifices, or uſe of frankincenſe, that prevailed among the Tuſcans in after ages, probably ſuggeſted this appellation to that people.

As each of the twelve tribes, or cantons, called in the Tuſcan language "Lucumonin," was governed by its own prince, a king preſided over the whole; and whilſt the lucumo aſſumed the adminiſtration of affairs in his own province, the king was conſulted on all extraordinary occaſions, and convened the general diet of the twelve nations on all preſſing emergencies. This diet was held at the temple of Voltumna, which was a celebrated city of Etruria, ſeated on the ſpot which is occupied, according to Cluverius, by the preſent city of Viterbo; and in this temple meaſures were concerted for making war upon, or concluding peace with their neighbours. Although the power of each lucumo was limited, the Etruſcan kings ſeem to have been veſted with a ſort of abſolute authority, conſonant to the firſt oriental form of government.

Some of the principal Tuſcan laws were ſuch as follow: 1. By the original conſtitution of Etruria, no ſingle ſtate, or lucumony, could enter upon a war, or conclude a peace, with any neighbouring power, without the participation of the whole Etruſcan body. 2. The Etruſcans, by a particular law (Athen. Deipnoſ. l. i. p. 23.) admitted their women to all nocturnal entertainments; in which they were afterwards followed by the Romans. 3. They obliged themſelves to treat all foreigners with the utmoſt humanity. 4. They gave all poſſible encouragement, as it ſhould ſeem, by virtue of their conſtitution, to all polite arts and artificers. 5. In order to deter people from contracting larger debts than they were able to pay, the Tuſcan boys, by way of ridicule, followed all inſolvent debtors with an empty purſe. 6. They muſt have had many good moral inſtitutions, ſince from them the Romans received a ſupplement to their Twelve Tables. 7. The jura fecialia were firſt obſerved by the Etruſcans. 8. The Etruſcan polity, in general, ſeems to have been founded upon maxims of the moſt conſummate wiſdom, as may be collected from Ariſtotle, and Heraclides Ponticus in Athenæus's Deipnos.; to which the curious reader may be referred for further information.

The religion of the Etruſcans was a groſs and multifarious idolatry. In common with the ancient Greeks, and Phœnicians, they worſhipped the Cabiri, or Dii magni majorum gentium. They were alſo initiated in the Samothracian or Cabirian myſteries.

Beſides the Greek and Roman deities, they had ſeveral peculiar to themſelves; ſome of which were confined to particular towns or diſtricts. The divine ſervice and ſacred myſteries of the old Etruſcans agreed, in ſeveral points, with thoſe of the Greeks, but in others differed from them, and theſe they communicated to the Romans long before that nation had any intercourſe with the Greeks. The feſtivals, holy days, and ſtated times of public worſhip of the Romans and Etruſcans, muſt alſo have agreed in ſeveral particulars, as the Romans, before they became acquainted with the Greeks, received every thing relating to religion, and even their calendar itſelf, from the Etruſcans. The latter borrowed of the Egyptians, or rather the Phœnician ſhepherds expelled Egypt, their public ſupplications, pomps, and ſolemn proceſſions, which occurred in ſome of their principal feſtivals. The rites and ceremonies uſed by the haruſpices, augurs, and pontifices at Rome, were derived from the Etruſcans, who ſeem to have been the moſt celebrated nation in the Pagan world for ſkill in augury, and divination, as well as knowledge of the nature of ſacrifices, to which all rites and ceremonies neceſſarily relate. This, however, was their character among the Romans, as Cicero and Livy have teſtified. Hence this branch of ſcience was emphatically ſtyled at Rome "Ars Etruſca," and "Diſciplina Etruſca;" ſo that Etruria was denominated by Arnobius' the mother of ſuperſtition. It is obſervable, that neither the Etruſcans nor the Romans had any magnificent temples in the earlier ages. The Etruſcans had ſome peculiarities in their religion, which diſtinguiſhed it from that of every other nation; but the ancient Egyptian and Phœnician modes of worſhip were the ſame with thoſe, for many of the earlieſt ages, uſed in Etruria; nor can any material difference be found between the oldeſt oriental and Etruſcan divinities. With regard to the theological notions of the Etruſcans, they believed one ſupreme Being, whom they called Jave, or Jove; they conſidered him as the great governor of the univerſe, as the principle of life and motion. They were firmly perſuaded of the immortality of the ſoul, and therefore believed a future ſtate of rewards and puniſhments; though in later times they ſeem to have followed the ſyſtem of Pythagoras, and conſequently to have adopted the metempſychoſis of that philoſopher. However, the generality of the Tuſcans adhered to the Sabian ſuperſtition, in common with moſt of the inhabitants of the Eaſt.

The Etruſcan language muſt have been the ſame, or nearly ſo, with the Hebrew and Phœnician. The firſt Pelaſgic ſettlements in Etruria could not have taken place many centuries after the deluge, and very few after the diſperſion; and at that time the languages, or rather dialects of the Egyptians, Aſſyrians, Babylonians, Celtes, Syrians, and Arabs, muſt have approached extremely near to the Hebrew and Phœnician, which the learned allow to have been almoſt the ſame. In ſhort both ſacred and profane hiſtory concur in ſhewing the Hebrew, Phœnician, and Etruſcan tongues to have been, in the earlier ages, nearly the ſame. This alſo appears from the letters and manner of writing anciently uſed in Etruria. The letters are almoſt the ſame with thoſe of the earlieſt Greeks, brought by Cadmus out of Phœnicia. The manner of writing is purely oriental, the letters being drawn from the right hand to the left, agreeably to the practice of the eaſtern nations. The former point is rendered indiſputable by the Eugubian tables, in conjunction with the Sigæan inſcription; and the latter by merely peruſing the Etruſcan inſcriptions. The very remote antiquity of the firſt colonies that ſettled in Etruria, as well as of the Etruſcan language and alphabet, may be eaſily inferred from theſe inſcriptions; for as the Pelaſgic alphabet, that prevailed in Greece before the age of Deucalion, conſiſted of ſixteen letters, the Etruſcan or Pelaſgic alphabet, firſt brought into Italy, compoſed only of thirteen letters, muſt have preceded the reign of that prince. The high, and indeed the almoſt incredible antiquity of the Etruſcan language and alphabet, has been clearly evinced in two diſſertations, printed at Oxford in the year 1746. For other particulars relating to this ſubject, we refer to Dempſter's "Etruria regalis," Gori in his "Muſeum Etruſcum," publiſhed at Florence in 1737; M. Bourguet's Diſſertation publiſhed in 1733, and Buonarota's of Florence in 1726; and Swinton's Etruſcan alphabet, publiſhed at Oxford; and for an abſtract, Anc. Un. Hiſt. vol. xviii.

The Etruſcans were extremely well verſed in all the arts of war and peace, and from them the Romans derived thoſe arts and ſciences that paved the way to the empire of the world. In the beſt ages of Rome, the Romans imitated the Etruſcans; nevertheleſs, in after-ages the Etruſcans became thoroughly debauched both in principle and practice. Augury, and every kind of divination; all the principal religious inſtitutions, temples, ſtatues of gods and heroes, the manner of forming or building cities, fortifications, conſecrations, and nuptial rites were tranſmitted to the Romans by the Etruſcans. Every thing alſo that bore any relation to civil government at Rome, ſuch as enſigns of royalty, the diſtinction of nobles from plebeians, the ſecures and faſces, the lictors, &c. was derived from the ſame ſource. Arms, inſtruments of military muſic, military accoutrements and decorations, trophies, triumphs, chariots, crowns, &c. and in ſhort every thing belonging to the art of war, or military exerciſes, that prevailed at Rome, were brought from Etruria. This was alſo the caſe with reſpect to money, locks and keys, lamps, candleſticks, glaſſes, cups, drinking veſſels, together with the laws and cuſtoms relating to banquets and entertainments. Agriculture, planting of vines, all inſtruments requiſite in huſbandry, mills, architecture, muſic, and a variety of muſical inſtruments, many ſorts of diverſions, eſpecially tragedies, various kinds of garments, and even the rudiments of phyſic, ſeem to have been introduced into Italy by the Etruſcans. Scenical amuſements, maſks, pantomimes, wreſtlers, the cuſtom of anointing their bodies, the uſe of wool, plaſtic ſtatuary, the fabulæ oſcæ or Atellanæ, nuptial verſes, or verſus Feſcenini, and the art of making earthenware, were alſo derived from the Etruſcans. The art of conſtructing ſhips and of navigating them, the method of equipping fleets, and all kinds of naval armaments, were known to the Etruſcans before the time of Romulus; and hence we may conclude, that this nation muſt have been a maritime power, and that it muſt have poſſeſſed an extenſive commerce in the earlier ages of the world. The Etruſcans, who were followers of Pythagoras, and who cultivated the principles of the Italian philoſophy, muſt have cultivated the art of muſic and poetry, and muſt have been well verſed in natural philoſophy and aſtronomy. Tragedy is ſaid to have owed its birth to this nation; or at leaſt they firſt communicated it to the Romans. The firſt actors who appeared upon the ſtage of Rome were ſent for from Etruria. Beſides, the ancient Etruſcans, valuing themſelves upon being the diſciples of Pythagoras, could not be ſtrangers to geometry, nor indeed to any of the mathematical ſciences. For military learning they were famous, and eſpecially for the art of drawing up an army, and making diſpoſitions for an engagement. Athenæus informs us, that the formation of the phalanx, and manner of fighting conſequent upon it, was invented by the Etruſcans, or at leaſt borrowed from them by the Romans. To all the other branches of literature and ſcience for which the Etruſcans were diſtinguiſhed, we may add that they excelled in the knowledge and compoſition of hiſtory.

The firſt perſon who fixed monarchical government in Etruria was Janus, ſuppoſed by ſome to be the Javan of ſcripture, or one of his poſterity, and in ſubſequent ages deified by his ſubjects as a ſingular benefactor. The hiſtory of their ſucceeding kings is intermixed with much fable, and, of courſe, very obſcure and uncertain. It appears, however, that they were a maritime power in the time of the Argonauts; and that they commanded reſpect as ſuch at leaſt a generation before the Trojan war, and made a figure at ſea before the Greeks. That the Etruſcans were a powerful and poliſhed nation, when Romulus founded or rather reſtored Rome, appears from ſome approved authors. That prince could not carry the deſign he had formed into execution, without the aſſiſtance of the Etruſcans. From them he derived all his civil and religious inſtitutions. Anc. Un. Hiſt. vol. xviiii.

ETSED, in *Geography*, a town of Hungary, 40 miles N.W. of Zatmar. N. lat. 48° 2'. E. long. 21° 51'.

ETTENHIEM, a town of Germany, in the biſhopric of Straſburg; 12 miles S.S.E. of Straſburg.

ETTENSTATT, a town of Germany, in the principality of Anſpach; 5 miles N.E. of Weiſſemburg.

ETTERSHAUSEN, a town of Germany, in the principality of Wurzburg; 3 miles N. of Volckach.

ETTLSTORFF, a town of the archduchy of Auſtria; 9 miles W. of Sonneberg.

ETTRICK, a river of Scotland, which originates in the S.W. angle of the ſhire of Selkirk, and runs N.E. augmented by many ſmall ſtreams in its progreſs through a pleaſant valley to the Tweed, into which it falls near Sunderland-hall, 1½ mile below Selkirk. The banks of this river were formerly ſhaded with woods, whence the county obtained the name of Ettrick foreſt.

ETUEND, a mountain of Perſia, in the province of Irak; 60 miles S.E. of Hamadan.

ETYMOLOGICON, is uſed for a book, containing the etymologies of many languages. See ETYMOLOGY.

ETYMOLOGY, (from the Greek ετυμος, *true*, and λογος, *a word*,) means a true or real account of words: and as this true account is obtained by tracing them to their origin, etymology hence ſignifies that part of grammar which teaches the derivation of words.

Etymology is an eſſential and uſeful branch of philology; but from partial views, and an inattention to the principles which it implies, it is regarded by many as the fruitleſs ſtudy of words, in which neither knowledge nor certainty is attained. In order to limit, as much as poſſible, the province of etymology, and to remove the objections which have been made againſt it, we ſhall here briefly ſtate the laws which direct, and the conſiderations which give it the preciſion and the fixedneſs of a ſcience.

1. Etymology implies a due attention to the ſtructure of the vocal organs, or to the affinities of elementary ſounds. All men have the ſame organs of ſpeech, and the ſame letters are ſounded by a ſimilar modification of thoſe organs. Letters pronounced by the ſame organs, or the ſame parts of the mouth, approximate in ſound to each other, and from this conſideration become more eaſily corrupted and changed one for another. Thus all the vowels, whatever peculiarity in character and ſound they preſent to a perſon familiar with them, have yet a cloſer affinity to each other than to other letters; and hence are even interchanged. The more modern art of printing, indeed, has contributed to fix the fluctuating ſounds of the vowels, by uniformly preſenting them to the eye under diſtinct characters; but ſtill in an etymological view they are utterly to be diſregarded, or to be regarded only as one capricious, ever fluctuating impulſe of the voice.

The juſtneſs of theſe obſervations will immediately appear to any one who conſiders thoſe words in Latin, which are evidently derived from the Greek; or thoſe in French and in Italian, which are derived from the Latin; or thoſe in modern Engliſh, which are borrowed from the Gothic and Saxon tongues, and are ſtill farther diverſified in the Scotch, Iriſh, and Welſh dialects.

While the vowels form, as it were, the ever corrupting fleſh, or the ever varying complexion of language, the conſonants are the ſinews and bones which impart to it ſtrength and firmneſs, and which alone render it a ſubject of philoſophical inveſtigation. But the conſonants have a cloſer alliance to ſome than to other letters; and their affinity depends on the manner in which they are enunciated. Thus, *p*, *b*, *f*, *v*, *w*, *m*, or φ in Greek, are kindred letters, being produced principally by the *lips*, and are therefore often changed one for another, as caprice or cuſtom ſhall dictate. The ſame obſervation holds in regard to the letters *ſ*, *t*, *d*, *r*, *l*, which being produced by the tongue, impreſſed in various degrees on the extremity of the upper teeth, are called *dentals*; to thoſe which are produced by the tongue and the roof of the mouth and the palate, ſuch as *g*, *j*, *z*, *ch*, and finally to the gutturals, which, though they exiſt not in our tongue, form an important claſs of letters in moſt other languages. To this diſtribution of the conſonants into *labials*, *dentals*, *palatines*, and *gutturals*, the ſcientific etymologiſt will pay a ſtrict attention, and obſervation will ſoon teach him that, however perfect any alphabet may be in regard to etymology, each claſs is but a variation of the ſame letter.

2. Etymology ſuppoſes a ſtrict attention to be paid to *analogy*, that is, to thoſe general principles by which any language is formed in regard to its internal ſtructure, to the diſtinguiſhing terminations of its nouns and verbs, to its general mode of combining words, and to thoſe changes which words uſually undergo after they have been imported and naturalized, as it were, from any foreign tongue. In order to diſcover the nativity and parentage of any term, we muſt, as it were, ſtrip it of the dreſs with which the cuſtom of the country has clothed it, and we can trace it to its true origin, only when we view it ſeparated from the termination by which it is diſguiſed: thus μηνη, when imported into Engliſh, appears under the form of *moon*, having dropped *η*, its peculiar termination; and when expreſſing that period of time which comprehends one revolution of the moon, it aſſumes the termination *th*, which the analogy of the language hath warranted *month*; while in Latin it exiſts in the ſhape of *men-ſis*. And here it is to be obſerved, that the general principles of analogy, as in natural philoſophy, ſo in etymology, are to be collected by *induction* from inſtances that are ſimple, unequivocal, and definite, and then applied to words that are not ſo. The propriety and juſtice of theſe remarks it will be neceſſary to illuſtrate by a few examples.

Suppoſe we were aſked the derivation of οινος, *wine*, ὁυ, or ἑ, *ſelf*; ανασσω, *to rule*, in Greek; we ſhould be able to aſcertain this only by unfolding a general principle in the ſtructure of that language. The oriental tongues, to which the Greek owes its origin, abound with gutturals, which by degrees ſoftened down into an aſpirate in many of thoſe words derived from them; while in others they melted into ſimple vowels, or were replaced by a labial, ſuch as φ, *f*, *b*, *v*, or *w*. Thus חי, *khee*, *life*, *ſelf*, became ὁυ, חאן, *khaan*, *a king*, ανασσω, *to rule*, and יין, *yeen*, οινος. In theſe derivations our conviction would be complete, becauſe it is juſtified by a general principle that holds in a thouſand other inſtances.

Suppoſe, farther, we were aſked what were the origin of the Latin *vicus*, *a village*; *video*, *to ſee*; *vinum*, *wine*; *ovis*, *a ſheep*; or of *wheel*, *year*, *well*, *weal*, in our own tongue; we anſwer that the ſubſtitution of a labial for an aſpirate or a guttural, or a diphthong, forms a general principle which pervades the Latin tongue in its formation from the Greek. Hence *vicus* is from οικος; *vinum* from οινος; *ovis*, from οις; *video* from ειδω. With reſpect to our own language a ſimilar analogy obtains, which has converted a guttural into a labial; thus *laugh* is pronounced *laff*; *enough*, *enuff*; and moſt of thoſe words which begin or end with *y* and *w*, whether derived from Hebrew, Greek, or Gothic, began or ended with a guttural. On this general principle *year* may ſafely be ſaid to be derived directly or indirecty from γυρος, *a circle*, and means a period or revolution of time; *wheel*, from κυλιω, *to roll*; *well*, from גיל, *geel*, *a fountain*; and *weal* from חיל, *kheel*, *ſtrength*, which alſo has given birth to the words *heal*, and *health*.

Moreover, if we were aſked the origin of *ſperno*, *to deſpiſe*, we ſhould ſay that it comes from πτερνη, *the heel*, for the prefixing of the letter *s* to Greek words is a principle that pervades the Latin tongue; thus the primary ſenſe of *ſperno*, is to put the heel upon; on the ſame principle is *ſalio*, *inſilio*, *inſult*, taken from ἅλλομαι. The French generally drop the gutturals either in the middle or at the end of words; hence we ſhould be juſtified by an invariable analogy in ſaying, that *eau*, *water*, is from *aqua*, and *ſeul* from *ſingulus*. The Italians generally drop the liquid *l*; agreeably to this cuſtom of the language, *fiume* is derived from *flumen*, *a ſtream*, and *piano* from *planus*, *a plain*. In German moſt of thoſe words which have *t* in Engliſh are uſed with an *s*; as *waſer*, *water*; *beſſer*, *better*; *es*, *it*: and the corruption of *m* into *f*, or *v*, is a principle that runs through the Welſh tongue; thus, *ve*, *voer*, and *vayr*, are but the Latin words *me*, *mare*, and *major*.

3. Etymology, in order to claim its proper rank as a branch of ſcience, requires a ſtrict attention to the *aſſociation of ideas*, the great law which regulates the human mind. The opinions and cuſtoms of men, it is well known, greatly influence their language; and this influence is produced by the ſecret and unerring impulſe of aſſociation; and the reaſon why this branch of philology has been ſo much abuſed or called in queſtion, is, that little or no regard has been hitherto paid to its connection with that grand invariable principle which governs the human underſtanding. He who attempts at etymology in any language muſt know the philoſophical, the religious, and the political notions of the people who uſe it; he muſt be acquainted even with the phyſical peculiarities of their country, and from an acquaintance with the laws of the human mind he ſhould be able to trace the ſecret proceſs by which thoſe circumſtances influence their ſpeech. We will give a few examples in illuſtration of theſe remarks.

In the early ages of the world, the principal idea under which the character of *God* preſented itſelf was that of *ſuperior power*; and, accordingly, the feelings which it awakened in the beholder were chiefly thoſe of *fear*. And even the Jews, who had far more rational notions of the Deity than the Gentiles, apprehended that no one could ſee God and live. Accordingly moſt of thoſe names, which ſignify a god, are in Greek either immediately derived from a word which ſignifies *fear*, or both from a common origin; thus, from באב, *baab*, *the firſt principle of things*, are taken φοιβος, ποποι, *Gods*; and φοβος, *fear*; ταρβος, *terror*, owes its origin to the Chaldæan תרף, *Terph*, *a houſehold god*. Παν, the god *Pan*, is only the Hebrew פון, *pon*, *conſternation*: δειμων is the *god of terror*, and hence δαιμων, *an inviſible ſpirit*, which was an object of *fear*, and δεισιδαιμων, *the fear of the dæmons*, *religion*. It was the common notion that thoſe dæmons produced violent paſſions and diſorders in the mind and body: hence came the verb δαιμοναω, *to be mad*. It was thought, too, that they were the agents of God in preſiding over men; hence ευδαιμων, *one who had a good dæmon for his guardian angel*, and κακοδαιμων, *one who had an evil one*.

The introduction of evil into the creation could not be accounted for by the heathen philoſophers, only by ſuppoſing the exiſtence of two principles equal in power, and oppoſite in character and operation. The good principle they naturally aſſimilated to the *ſun*, the moſt ſplendid body in nature, whilſt the evil they called *darkneſs*; hence the ſaying *God is light*: צי, is pronounced by the Perſians *tzee*, but by the Arabians *tdee*, or *tdeio*, *light*; hence ζευς from the former mode of pronunciation, and θεος from the latter. On this principle the Chaldean אזא, *aza*, *to make hot*, the action of the ſun, gave birth to ἅζω, *to worſhip*, or *reverence*. The general opinion among the philoſophers was that water is the firſt principle of things. Hence the Arabic *mao* came, in Perſian, with little variation, to ſignify *fruit*, *wine*, and in Greek, μαια, *the goddeſs of birth*, and in Engliſh the producing month, *May*. The ſame word in Hebrew, by aſſuming *t* after the analogy of feminine nouns, is מות, *mot*, *death*, which means *reſolution into water*; hence the Egyptian *mot*, (whence Moſes is ſuppoſed to have been taken,) and *mud*, what is waſhed together by water, juſt as *lutum*, *clay*, is the ſupine of *lavo*, or *luo*, *to waſh*.

In eaſtern countries, where the heat of the ſun is violent and long continued, rain is deemed the greateſt bleſſing, and all the terms expreſſive, in moſt of the Aſiatic tongues, of plenty, ſucceſs, and joy, are generally borrowed from the names of water; hence the Hebrew ברך, *berek*, *to bleſs*; in Greek is βρεχω, *to rain*; in Latin *precor*, *to aſk for bleſſing*, *parco*, *to give bleſſing*; *ſpare*, and *ſpargo*, *to ſhed as the dew*, *or ſcatter as ſeed*. The ſame root exiſts in Engliſh in the form of *brook*, the effect of rain.

4. Etymology, in order to become a rational ſtudy, implies an extenſive and an accurate acquaintance with languages. It is not ſufficient to be acquainted with Latin to know Greek; nor to know Italian to be acquainted with Latin, nor to know Engliſh to be acquainted with the Saxon or Gothic; but to be a good etymologiſt in either of theſe, a man muſt comprehend them all. So manifold is the intercommunity between all languages, that no language exiſts derived from one and the ſame ſource. Words exiſt in Engliſh which exiſt alſo in moſt other tongues, under differences of character and termination; and they are derived not from each other, but from a common origin; and a ſcientific etymologiſt, inſtead of deriving them from each other, will trace them all till they meet in a few primitive terms. It would probably be wrong, or at leaſt it would be very doubtful to ſay, that *hand* comes from the Latin obſolete *hendo*, *to catch with the hand*, or from χανδω, the parent of *hendo*, but it would be right to ſay that theſe are *connate*, or *kindred* terms, ſprung, if not from each other, from ſome common root. In Hebrew, Perſian, and Arabic כף, *caph*, *is the hand*. The action of this is two-fold, as it *imparts*, or as it *receives*. In the former ſenſe it gave birth to the Saxon or Gothic *giff*, and hence *if*;—in the latter to *capio*. *To take in hand is to begin a thing*; hence the ſame word exiſts in the form of *Cæpio*; and paſſing into Greece it produced κωπη, *a handle*.

And here it is obvious to remark, that as the root, paſſing into different countries, produces as it were new branches; thoſe branches will not continue long till they in their turn become the ſtems of more numerous and diverſified ſhoots; and as they thus multiply by accident, the progreſs of knowledge, the multiplication and diſtinction of ideas attendant thereon, ſeize, as it were, theſe wild and promiſcuous offspring, and give them the ſanction of cuſtom, the ſupreme arbiter of ſpeech, thus conſidering as genuine, words which at firſt were mere *corruptions*. Thus in our own tongue *guſt* is wind; hence *ghoſt*, what conſiſts of *wind*, *ſpectre*, *a-ghaſt*, *ghoſtly*, like a ſpectre, and *gas*, an aeriform fluid, ſo denominated from ghoſt, firſt by Van Helmont. Thus alſo in Latin, from πηγω, *to join together*, is *pango*, *to faſten*, *paco*, *to unite in concord*, *pacify*. To paint is to faſten adventitious colours on a thing; hence *pingo*, and to give to falſehood the adventitious colours of truth is *fingo*, *to feign*. Again, from μενος is *men's mind*, *force*, *eſſence*, *memini*, *to call to mind*, *moneo*, *to put in mind*; *manus*, *force*, or that organ in which the ſtrength of the human body chiefly conſiſts, *manes*, *the ſouls or departed ſpirits*, ſpirit being the eſſence of man; and *maneo*, *to exiſt*, the ſoul being that which exiſts after the deſtruction of the body.

Etymology, then, to be raiſed above the caprice of fruitleſs ſtudy, and to be claſſed among the uſeful and ſolid branches of ſcience, muſt be founded on a juſt regard to the affinities of letters, and to the ſtructure of the organs of ſpeech. It ſuppoſes an acquaintance with the philoſophy of the human mind; with the analogies which form and diſtinguiſh each language; with the hiſtory of mankind, philoſophical, religious, and political. From theſe, its qualifications, reſults its utility as a department of human knowledge. Etymology, it is evident, furniſhes the readieſt and moſt effectual means to acquire the knowledge of language; and as language is but the dreſs of our ideas, it holds up a mirror to delineate and reflect the operations of the human mind. It helps to aſcertain the poſitions of ancient places, to clear obſcurities in the antiquities of nations and families. What is more, when confined within its proper limits, and purſued to its full extent, it will throw much light and additional evidence on the truth of the Moſaic hiſtory, reſpecting the origin and propagation of mankind.

EU, or Eo, in *Geography*. See Eo.

Eu, a ſea-port town of France, and chief place of a canton, in the department of the Lower Seine, and diſtrict of Dieppe, ſeated on the Breſſe, near the coaſt of the Engliſh channel; 15 miles N. of Dieppe. The place contains 3400 and the canton 12,810 inhabitants, on a territorial extent of 182½ kiliometres; and in 27 communes.

EVA, in *Ancient Geography*, a town of the Peloponneſus, in Arcadia.—Alſo, a hill of the Peloponneſus, in Laconia, near Sellaſia. Polybius.

EVACUANTS, in *Medicine*, are thoſe remedies which operate by diminiſhing the quantity of fluids in the body. This effect may be produced either directly, by an artificial opening into the veſſels or cavities containing the fluid to be evacuated; as by blood-letting, by means of the lancet, or by cupping; by tapping; &c. Or the evacuation may be accompliſhed indirectly, by exciting the action of the veſſels, which are naturally deſtined to throw off redundant fluids, on the one hand; or by producing inflammation, and a conſequent diſcharge of fluids, from parts not naturally ſecreting them. Evacuants acting upon the natural emunctories, as the organs of excretion have been called, are of various quality and denomination, according to the parts upon which their action is exerted: thus, ſome ſtimulate the veſſels which open into the cavity of the inteſtines, and carry off the fluids by ſtool, and are called *purgatives*, *laxatives*, or CATHARTICS; others excite the veſſels of the kidnies to increaſed action, and are denominated DIURETICS; others augment the perſpiration, and are termed DIAPHORETICS and *ſudorifics*; others again ſtimulate the ſalivary glands, and produce a great diſcharge of ſaliva, whence they are called SIALOGOGUES; and others excite an increaſed diſcharge of the mucus of the noſtrils, and are termed ERRHINES. All theſe kinds of evacuant medicines are occaſionally employed, with a view to relieve the conſtitution at large, or ſome part of the body, from an inflammatory or febrile condition; or to remove local congeſtions in particular organs, &c. See BLEEDING, CUPPING, and the words in capitals; under which heads the principles of the evacuation, thus variouſly effected, are explained.

EVACUATION, ſee the preceding article.

Evacuation, in a *Military Senſe*, relates to the withdrawing of troops from any fortreſs or poſt, not beſieged, but intended to be relinquiſhed, or eventually to be diſmantled. This term is ſometimes erroneouſly uſed in capitulations, where it is expreſſed that the garriſon ſhall evacuate within a certain number of hours. Now, as it is in almoſt every caſe, a ſtipulation on the part of the victors, that they ſhall be put in poſſeſſion of certain gates, or defences, previous to the garriſon marching out; thereby ſecuring every advantage that may have been obtained; it ſtands to reaſon, that the term evacuation is incorrectly applied. We have, indeed, but rarely inſtances wherein it is properly introduced; one very recent caſe is however very prominent; namely, the evacuation of certain fortreſſes in Pruſſia by the French troops; for, if we are correctly informed, the Pruſſian forces did not, in ſome inſtances, attempt to enter until their *friends* had completely withdrawn.

It is ſometimes made a condition, that particular approaches, lines, or poſts, ſhall be evacuated; there we ſee the term appropriately uſed; becauſe ſuch approaches, and lines eſpecially, are not conſidered as permanent works; therefore are intended to be diſmantled ſo ſoon as thoſe who erected them ſhould retire.

Where a place is to be evacuated under the expreſs condition of all damages being paid for, it becomes the duty of the future poſſeſſors to be very correct in cauſing an enquiry to be made into all depredations and grievances, before the forces about to retire quit the place. Commiſſioners on both ſides are neceſſary; in order that every matter may be adjuſted at the moment, ſo as to obviate future diſagreements. This appears to have been attended to when the Portugueſe territory was evacuated by Junot; though we have ſtrong reaſon to apprehend that great evaſion, and many highly nefarious acts, were practiſed by the French on that occaſion.

EUÆMIA, of ευ, *well*, and αιμα, *blood*, is uſed by Tremelius and ſome other writers, to denote a good and healthy ſtate of the maſs of blood.

EUÆMON, in *Ancient Geography*, a town of Greece, placed by Steph. Byz. in the territory of the Orchomenians.

EVAGRIUS, in *Biography*, patriarch or biſhop of Conſtantinople, who ſucceeded Eudoxus in 370, and whoſe election was much reſented by the emperor Valens. From this event commenced a cruel perſecution againſt the Catholics, which did not terminate till the acceſſion of Gratian to the throne. Evagrius probably died in exile during this period.

Evagrius, biſhop of Antioch, ſucceeded Paulinus in the year 389; in conſequence of whoſe election, in oppoſition to Flavianus, the ſchiſm in the church of Antioch, that has been much lamented by the orthodox, was continued. However, by the influence of Siricius biſhop of Rome, in the council of Capua, held in 390, Evagrius's election was approved. Two years afterwards Evagrius died, and the ſchiſm terminated. Evagrius was the friend and companion of St. Jerome, who repreſents him as a perſon of an active and ardent ſpirit, and as the author of various writings, which he had peruſed. None of theſe that deſerve particular mention are now extant. Cave. Dupin.

Evagrius, ſurnamed *Ponticus*, and by St. Jerome *Hyperborita*, on account of the ſituation of the place of his nativity near the Euxine ſea, flouriſhed near the cloſe of the fourth century. Having been ordained deacon of Conſtantinople by St. Gregory Nazianzen, he was inſtructed by this biſhop in biblical learning, and advanced to the office of his archdeacon. His perſon and manners recommended him to the favour of the ladies; and being ſuſpected of an improper intimacy with the wife of a man of conſequence, he was obliged to retire from Conſtantinople in the year 385, and to remove to ſome diſtant place. At Jeruſalem he embraced the monaſtic life, and paſſed 15 years at a monaſtery amidſt the deſerts of Nitria in Egypt.

Whilſt he was in this ſituation he refuſed the epiſcopal dignity which was offered him by Theophilus biſhop of Alexandria. He afterwards defended the opinions of Origen, and laid the foundation of the tenets which, in the courſe of a few years, were propagated by Pelagius and his followers. He lived to an advanced age, but the time of his death has not been aſcertained. Sozomen ſpeaks of him as a man, diſtinguiſhed by his learning, judgment, and eloquence; and repreſents him as devout, humble, abſtemious, and irreproachable in his manners. Some of his writings are found entire in the "Bibliotheca Patrum," and in "Cotelerius's Monum. Eccl. Græc.;" but fragments only of the greater number are diſperſed in the works of Socrates and other authors. Socrates' Hiſt. Eccl. Cave. Dupin. Another monk of this name flouriſhed among the eccleſiaſtical writers of the fifth century. Cave. Dupin.

Evagrius, an ancient eccleſiaſtical hiſtorian, was born at Epiphania, a city of Syria in 536 or 537. From the ſtudy of rhetoric and the profeſſion of an advocate, in which he acquired conſiderable reputation, he derived the ſurname of *Scholaſticus*. At Antioch he lived in habits of intimacy with Gregory, patriarch of that city, and when Gregory was charged with the crime of inceſt, and made an appeal to the emperor and a ſynod, Evagrius attended him to Conſtantinople, where his abilities and character were held in high eſtimation; nor was he leſs reſpected at Antioch, the place of his cuſtomary reſidence. The intervals of leiſure which he could gain from the public duties of the ſeveral offices which he ſuſtained, were devoted to the compoſition of his "Eccleſiaſtical Hiſtory, in 6 books," comprehending the period from the year 430 to 594, and including the events that occurred from the cloſe of the hiſtories of Theodoret and Socrates till the twelfth year of the emperor Mauricius. His books of "Epiſtles, &c." and "Panegyrical Oration on Mauricius," &c. are loſt. His hiſtory is, upon the whole, a work of induſtrious reſearch, general information, and conſiderable merit; though it manifeſts, on the part of the author, a great degree of credulity. The writers of the Romiſh church extol him as the only Greek eccleſiaſtical hiſtorian who has maintained the doctrine of the true faith; and Photius repreſents his ſtyle as ſometimes elegant and beautiful, often too redundant and luxuriant.

The original Greek of this hiſtory was publiſhed at Paris in 1544, in folio, by Robert Stephens; in 1612 at Geneva, in folio, accompanied with a Latin verſion; in 1679 by Valeſius, with a new verſion and notes; and in 1720 this laſt edition was republiſhed at Cambridge in folio, with many additional notes. Cave. Valeſii Præf. Dupin.

EVANDRIA, in *Ancient Geography*, a ſmall town of Spain, in Luſitania, according to Ptolemy; ſuppoſed to be "Talavera la Veja."

EVANDRIUS Mons, one of the ſeven mountains, forming the ſite of the city of Rome, called alſo mount Palatine.

EVANGELICAL *Harmony* and *Economy*. See the ſubſtantives.

EVANGELISTS, the inſpired authors of the Goſpels. See Matthew, Mark, Luke and John. The ſymbols of theſe in the order now recited, according to Jerom, are a man, a lion, a calf or ox, and an eagle. According to St. Auguſtine, in his interpretation of Ezekiel, ch. i. 5.—10. and Rev. iv. 7, they are a lion, a man, an ox, and an eagle.

The word is derived from the Greek, ευαγγελιον, formed of ευ, *bene*, *well*, and αγγελος, *angel*, *meſſenger*.

The denomination evangeliſts was likewiſe given in the ancient church to ſuch as preached the Goſpel up and down, without being attached to any particular church, being either commiſſioned by the apoſtles to inſtruct the nations, or of their own accord, abandoning every worldly attachment, conſecrated themſelves to the ſacred office of preaching the Goſpel.

In which ſenſe ſome interpreters think it is that St. Philip, who was one of the ſeven deacons, is called the evangeliſt, in the twenty-firſt chapter of the Acts of the Apoſtles, ver. 8. Again, St. Paul writing to Timothy, Ep. ii. chap. iv. ver. 5. bids him do the work of an evangeliſt. The ſame apoſtle, Eph. iv. 11. ranks the evangeliſts after the apoſtles and prophets.

Evangelists, in *Geography*, four ſmall iſlands at the weſtern extremity of the Straits of Magellan, near the coaſt of South America; three are low, and one, at ſome diſtance, appears like a hay-ſtack. S. lat. 52° 45′. W. long. 67° 16′.

EVANIA, in *Entomology*. See Sphex.

EVANID, a name which ſome authors give to thoſe colours which are tranſient, or not of long duration; as thoſe in the rainbow, in clouds, before and after ſun-ſet, &c.

Evanid colours are the ſame with thoſe otherwiſe called fantaſtical and emphatical colours. Some authors alſo uſe the ſame term to expreſs thoſe flowers of plants whoſe petals fall off as ſoon as they are opened.

EVANS, John, in *Biography*, was born at Wrexham, Denbighſhire, in the year 1680. His father was one of the ejected miniſters in 1662, who, on account of his nonconformity, being driven from the eſtabliſhed church, became miniſter to an independent congregation at Wrexham. The ſon was educated with great care, and inducted to the different branches of literature neceſſary to qualify him for the office of the miniſtry, which he afterwards exerciſed in London, firſt as an aſſiſtant, and afterwards as ſucceſſor to Dr. Daniel Williams. He died in the year 1730, in the fifty-firſt year of his age, highly eſteemed by all who knew him. He had ever been eminent for piety, integrity, and public ſpirit; in his principles he was orthodox, but diſpoſed to think well of, and to honour, thoſe who differed from him, without any regard to the ſentiments which they might hold. He received a diploma of doctor in divinity from the univerſities of Edinburgh and Aberdeen. His principal work as an author conſiſted of two volumes of ſermons, entitled "Practical Diſcourſes concerning the Chriſtian Temper," which are ſtill in conſiderable eſtimation. The celebrated Dr. Watts characterized them as "the moſt complete ſummary of thoſe duties which make up the Chriſtian life." Gen. Biog.

Evans's *iſland*, in *Geography*, a ſmall American iſland, near the coaſt of Main. N. lat. 44° 31′. W. long. 67° 3′.

EVANSHAM, a town of America, the capital of Wythe county, in Virginia, ſituated on the E. ſide of Reedy creek, which falls into the Great Kanhaway, Woods or New River. It contains a court-houſe, gaol, and about 25 houſes; 40 miles W. by S. from Chriſtianſburg.

EVANTES, in *Antiquity*, the prieſteſſes of Bacchus, thus called, becauſe in celebrating the orgia they ran about as if diſtracted, crying *evan, evan, ohe evan!*

The word is formed from Ευαν, a title or appellation of Bacchus.

EUANTHI Colores, in *Painting*, a term uſed by the Greeks to expreſs what the Romans call the *floridi colores*; theſe were ſuch colours as had a remarkable brightneſs in their works. The other duller and coarſer colours the Romans called *auſteri colores*, and the Greeks *bathyi*.

Of the firſt ſort were cinnabar, lapis armenus, chryſocolla, minium, indigo, and purpuriſſa, according to the Romans; but the Greeks, as we find by Dioſcorides, made cinnabar one of the auſtere colours.

EUAPHION, (from ευ, *eaſe*, and αφη, *the touch*,) in *Surgery*, a medicine for the hemorrhoids, named from its gentleneſs. Galen.

EVAPORATION, in *Natural Philoſophy*, is that proceſs by which water and other liquids are converted into vapour or ſteam, an elaſtic fluid, and diſſipated in the atmoſphere. Certain ſolid bodies, too, are ſubject to a ſimilar diſſipation in air; this is uſually denominated *exhalation*: but as the cauſe is no doubt the ſame in both caſes, it may be properly conſidered under this head.

The ſpontaneous evaporation of water, or that which is conſtantly going on in a greater or leſs degree from all parts of the ſurface of the globe, has always been an intereſting phenomenon to the ſpeculative philoſopher. Various hypotheſes have been advanced to account for the aſcent of water into the atmoſphere in an inviſible form, and for its ſubſequent deſcent in the form of rain; but the opinions of early writers on this ſubject are of little importance, as they were not acquainted with the principal facts and experiments which ought to guide us in the inveſtigation. Ariſtotle ſeems to have aſcribed the formation of vapour to the action of fire; and ſo far his notion was correct. Halley ſuppoſes ſmall hollow ſpheres of water to be filled with a ſubtile elaſtic fluid, ſo as to make them ſpecifically lighter than air; he alſo hints at a chemical affinity between air and water, ſimilar to that between water and ſalts. Deſaguliers, after having ſhewn the inſufficiency of former hypotheſes, propoſes a new one; he aſſerts that water is capable of being converted by heat into an elaſtic fluid much lighter than air, and refers to the ſteam engine as a proof; he ſhews, too, that a glaſs veſſel filled with water, and inverted in another veſſel of water, and then expoſed to the heat of ebullition, has its water expelled, and ſteam, an elaſtic inviſible fluid, takes its place. This ſteam, he ſhews, is again condenſed into water as the veſſel cools. He argues that ſteam is $16\frac{1}{2}$ times lighter than air, and that when formed at a low temperature it muſt aſcend in the atmoſphere till it meets with air of the ſame denſity, and there it will ſtop; but when accumulated, the cold condenſes a portion of it into drops of water: hence clouds and rain. This notion, which goes to identify vapour in the air, with the ſteam or vapour of water formed by heat in a vacuum, is ingenious and apparently original, but how the vapour ſhould aſcend till it arrives at air of the ſame denſity, is not very eaſily conceivable: for the vapour, in aſcending, muſt expand as the preſſure is diminiſhed, according to the eſtabliſhed laws of elaſtic fluids, and therefore never can obtain the ſame denſity as the air. The vapours might indeed aſcend to the top of the atmoſphere, and form a diſtinct ſtratum, as ſome have imagined with reſpect to hydrogen gas. The author has extravagantly under-rated the ſpecific gravity of ſteam, or aqueous vapour, which is certainly at leaſt one-half that of atmoſpheric air. Upon the whole, this hypotheſis was more plauſible than that adopted by Halley.

As the ſcience of chemiſtry gradually expanded, the phenomena of evaporation began to be conſidered as moſt nearly allied to thoſe of chemical ſolution. From the year 1743 to 1766 the eſſays of Nollet, Franklin, Roi, Hamilton and others, tended to eſtabliſh the opinion that water is taken up into the air by chemical ſolution, in a ſimilar way to that in which water and other liquids diſſolve ſalts. In the 55th vol. of the Philoſophical Tranſactions, there is an eſſay of Profeſſor Hamilton on evaporation, in which he inſiſts at large on the hypotheſis of ſolution. Hot water, he obſerves, diſſolves ſalts ſooner and in greater quantities than cold water, and depoſits a part of the ſame on cooling: ſo warm air takes up more water than cold air; but the water is depoſited again when the air cools, or by the contact of a cold body, as a glaſs of cold water. Evaporation always produces cold; this is obſerved when any part of the human body is moiſtened with water, and the ſame ſuffered to evaporate, but ſtill more remarkably when moiſtened with ether or other fluids more evaporable than water; in like manner, certain ſalts diſſolved in water conſtantly produce cold. In ſhort, the points of reſemblance between evaporation and chemical ſolution are ſo numerous and ſtriking, that the generality of philoſophers ſeem to have adopted the idea that air poſſeſſes a chemical affinity for water, and attaches a portion of it to itſelf, which becomes incorporated with the elaſtic maſs of the atmoſphere, under the denomination of vapour, till cold, or ſome other cauſe, reduces it again to the ſtate of water.

In the year 1783, Sauſſure of Geneva publiſhed his celebrated eſſays on hygrometry, in which the ſubject of evaporation is diſcuſſed much more largely than had been previouſly done. This author does not claim the merit of any new theory; for, he ſays, "the converſion of water into elaſtic vapour has been known time immemorial; the diſſolution of water in air was diſcovered by Roi, and the veſicules, which compoſe fogs and clouds, were conceived by Halley, and ocularly demonſtrated by Kratzenſtein. But no philoſopher has, I believe, clearly diſtinguiſhed the different modifications of vapours: all the ſyſtematic authors have endeavoured to reduce all vapours to one and the ſame ſpecies, whilſt in reality they exiſt under forms abſolutely different. It had not been perceived that water, on being diſſolved in the air, is converted into an elaſtic fluid; but I have ſhewn this to be the fact by the moſt exact experiments; and further, the preciſe effect which the ſolution of a given quantity of water in air has upon the ſpecific gravity of the air. Finally, the laws according to which the humidity of the air varies in proportion to its condenſation and rarefaction, form an entirely new ſubject, on which our ideas hitherto have been vague and erroneous. Theſe, I believe, will be found to have received a ſatisfactory elucidation." Preface, page 10. Before we examine the concluſions of Sauſſure, it may be proper to advert to the facts which are alluded to above. Having procured a large glaſs balloon, containing $4\frac{1}{4}$ cubic feet of air, Sauſſure adapted to it a manometer or inſtrument to meaſure the force of elaſtic fluids; the balloon being filled with air of the natural humidity, the manometer, or thermometer, and a veſſel containing cauſtic alkali of a given weight, were all encloſed in the balloon, and confined from the action of the external air. The cauſtic alkali abſorbed the vapour in the balloon, and the manometer ſhewed the diminution of elaſticity conſequent thereon; after the experiment was carried as far as was deſired, the balloon was opened, and the increaſe of weight of the alkaline veſſel was aſcertained. Hence were derived data for calculating the influence of vapour on the elaſticity of the air, and likewiſe the whole quantity of water in a ſtate of vapour in a given bulk of air. This might be called the analytic experiment; but the ſynthetic one was alſo made. By encloſing a piece of wet linen of a given weight in the balloon containing air as dry as poſſible, along with the other inſtruments, the moiſture of the linen evaporating increaſed the elaſticity of the confined air a quantity which could be obſerved; and at the cloſe of the experiment the loſs of weight of the linen indicated the quantity of water which had been evaporated, and had increaſed the elaſticity. The two methods were thus found to corroborate each other remarkably well. The reſults were, that at the temperature of 64°, a quantity of extremely dry air acquires an increaſe of $\frac{1}{34}$th in elaſticity in attaining extreme humidity; and *vice verſâ*: that a cubic foot of air takes up 10 grains of water in paſſing from extreme dryneſs to extreme humidity; and that conſequently it diminiſhes the ſpecific gravity of the air, as if a volume of elaſtic fluid, equal in weight to 10 grains, and of $\frac{3}{4}$ths the ſpecific gravity of air were added to it. Of the general accuracy of theſe reſults there is no room for doubt. They form a valuable acquiſition to this branch of ſcience. One important fact was ſtill wanting; as air was ſuppoſed to diſſolve water by virtue of an affinity, it was reaſonable to expect that every ſpecies of air would have its peculiar affinity, or take up a certain portion of water peculiar to itſelf, agreeably to what is obſerved in other caſes of chemical ſaturation. Sauſſure aſcertained this point clearly in regard to inflammable and fixed air, that is, hydrogen and carbonic acid. Both theſe gaſes were found in their pure ſtate, and when mixed with any proportion of common air, to affect the hygrometer in the ſame way as common air, and to promote evaporation in the ſame degree. In ſhort, there was not any appearance to indicate that they contained either leſs or more vapour than common air in like circumſtances. Sauſſure found that evaporation was accelerated in proportion to the rarefaction of the air; this circumſtance he accounted for by obſerving that the preſſure of the atmoſphere retards evaporation; however, upon the principle of ſolution, it might have been expected that the greater quantity and denſity of the ſolvent would have compenſated for the greater preſſure. The condenſation of air, on the contrary, uniformly tends to make it depoſit moiſture, and retards evaporation. This he explains by obſerving, that the ſolvent power of air does not increaſe quite ſo rapidly as its denſity; continued condenſation therefore muſt firſt ſaturate the air with moiſture, and then make it depoſit a portion. Sauſſure found that warm and denſe air required more vapour to ſaturate it than cold and rare air; he was led too haſtily to aſcribe the ſolvent power of the air partly to its temperature and partly to its denſity; but it has ſince been proved that temperature alone is concerned, and the denſity has no effect whatever. On the head of rarefaction and condenſation, Sauſſure adverts to a curious fact, known by every philoſopher, but not ſatiſfactorily explained by any one; namely, the abundant and inſtantaneous formation of a cloud or miſt upon exhauſting a receiver by the air-pump. As the rarefaction of air is found to promote evaporation, it appears aſtoniſhing at firſt ſight that the air ſhould exhibit ſigns of ſuperſaturation at the ſame inſtant. When the pump plate is covered with wet leathers the above appearance never fails; but the abbé Nollet found it to take place when water was totally excluded. Sauſſure, however, denies this to be the fact; he thinks that water muſt not have been excluded with ſufficient care in Nollet's experiments; and affirms that from his own experience no appearance of miſt was found upon exhauſtion, when the pump was carefully dried. The hygrometer at the time was 70°, extreme moiſture being 100°. As the two authors here appear to be at iſſue as to the fact, the writer of this article, from his own experience, can venture to affirm that both of them may ſtill be correct. When care is taken to exclude water from the pump and receiver, the miſt is by no means ſo copious as otherwiſe; it is alſo more diminutive as the air is dry or far from extreme humidity; with both theſe circumſtances and a large receiver, no miſt will appear by a moderate rate of exhauſtion; but it may always be produced by uſing a ſmall receiver, and rapid exhauſtion. Sauſſure's explanation of the fact is very inadequate, and unworthy of repetition; he further notices the dew obſerved on the receiver of an air-pump after letting in the air, and very juſtly aſcribes it to the condenſation of the vapour raiſed up into the receiver after exhauſtion; the air taking in with it nearly as much vapour as it is capable of holding. Upon liberating condenſed air a great miſt is obſerved in the receiver; Sauſſure explains this in the ſame unſatisfactory manner as before, and that in one caſe only, namely, when the receiver contains water; but his explanation does not apply when the receiver is perfectly dry; yet the phenomenon of miſt is equally apparent in that caſe. The true explanation is, that a great but momentary cold, of 50° or more, occaſions the precipitation of vapour, both upon rarefying air and liberating condenſed air. The fact has ſince been demonſtrated by Mr. Dalton; but it was hinted at by Lambert, as quoted by Sauſſure, page 331.

Though Sauſſure does not affect to introduce any new theory on the ſubject of evaporation, he certainly advances ſome notions on the ſubject that were not previouſly held by others, eſpecially by thoſe who adopted the chemical ſolution of water in air. He ſays, "evaporation, properly ſpeaking, is the reſult or rather the effect of the intimate union of elementary fire with water; by this union the water and fire combined form an elaſtic fluid ſpecifically lighter than air, and which is peculiarly diſtinguiſhed by the name of *vapour*. This vapour being formed in a vacuum, or otherwiſe when the heat is ſufficient to give it force ſuperior to atmoſpheric preſſure, ſo as to expel the air from any veſſel in which it is formed, is called *pure elaſtic vapour*." Page 361. This repreſentation is, in all probability, correct, and will be generally adopted without heſitation. He proceeds: "but when the vapour cannot entirely ſurmount the preſſure of the air, it penetrates it, mixes with it, undergoes a true ſolution, and may then be properly called *diſſolved elaſtic vapour*." Page 362. Certainly the advocates for the ſolution of water in air cannot adopt this language. Pure elaſtic vapour is firſt formed; then by means of ſuch force as it happens to have, which is generally ſmall, it penetrates and mixes with the air; afterwards it is diſſolved by the air; that is, the particles of air finding thoſe compound particles of water and fire amongſt them, attract them, and form triple compounds of air, water, and fire. Here the buſineſs for which ſolution is called in is performed beforehand; for we muſt ſuppoſe it to be the affinity of air for water which enables the latter to riſe at all againſt ſo ſuperior a preſſure. If the vapour can, by virtue of its elaſticity, penetrate the air, why may it not continue there by virtue of the ſame elaſticity? Sauſſure proceeds; "when afterwards the air ſaturated lets fall the water which it contains, this water ſometimes takes the form of veſicules or bubbles; theſe veſicules, filled and ſurrounded with a ſubtile elaſtic fluid, are ſupported in the air, and even ſometimes riſe in it, by their leſs ſpecific gravity. Theſe veſicules are eſſentially diſtinct from the air, as well as from the vapour above defined; but according to cuſtom I have arranged them in the claſs of vapours, and diſtinguiſhed them by the name of *veſicular vapour*. Finally, when the elaſtic vapour, or the veſicules themſelves, condenſe into ſolid drops, which only differ from drops of rain by their extreme ſmallneſs, they are ſtill very different from vapours properly ſpeaking. Notwithſtanding, as theſe ſmall particles float in the air, and can even be ſupported in it for ſome time, by its agitation and viſcoſity, I have claſſed them alſo amongſt vapours, and given them the name of *concrete vapours*."

Page 363. It may be proper to obſerve here, that the veſicular vapour of Dr. Halley was ſuppoſed to be tranſparent, and therefore to correſpond to the *diſſolved elaſtic vapour* of Sauſſure. It was moreover hypothetical; but Kratzenſtein and Sauſſure affirm that the ſmall viſible particles floating over ſteaming water, as well as thoſe of certain fogs, are diſcernible by a microſcope to be hollow or veſicular. Theſe viſible particles are the *veſicular vapour* of Sauſſure. Though it is by no means improbable that the vapour iſſuing from warm water is enveloped in a film of water, juſt as we ſee it in ebullition, and that the ſame bubble of ſteam on cooling may ſhrink into a veſicule, containing an atom of air, the original nucleus of the ſteam; yet it is not equally probable that in the condenſation of pure vapour a veſicule ſhould be formed: ſtill leſs likely is it that ſometimes veſicules, and at other times ſolid drops, ſhould be formed. Microſcopic obſervations on atoms dancing about in the air are ſcarcely to be relied on. But whatever may be the fact as to the conſtitution of condenſed vapour, that is, whether the particles are hollow or ſolid, there is not any ſufficient reaſon for ſuppoſing them conſtituted of any other principles than water and atmoſpheric air. The only one that has been advanced in ſupport of the hypotheſis is, that without ſome ſubtile elaſtic fluid, internal or external, the watery particles conſtituting clouds muſt conſtantly deſcend; whereas clouds are ſeen to remain ſtationary and ſometimes even to aſcend, which, it is alleged, could not take place, were not the particles of leſs ſpecific gravity than the air. Now the aſcent of clouds is in all probability an optical deception. It is occaſioned by the diſſolution or evaporation of the under ſurface of the cloud, and the ſuperior new formation of a cloud. We have no ſufficient reaſon for believing that the individual particles of clouds aſcend; yet they frequently deſcend with a velocity almoſt imperceptible; this ariſes from the reſiſtance the air makes to the motion of ſmall bodies, which, it is well known, increaſes in proportion as their diameters decreaſe. The epithet *vapour*, which denotes an elaſtic fluid, cannot, with philoſophical propriety, be applied to the viſible particles of water conſtituting clouds.

Mr. Pictet of Geneva publiſhed an ingenious eſſay on fire, which was tranſlated into Engliſh and publiſhed in 1791. This gentleman, impreſſed with ſuch ideas of the powers of fire in every thing which relates to evaporation, is tempted to look upon it as the ſole agent in this claſs of phenomena, and to renounce the idea that air acts in the manner of chemical *diſſolvents*. He obſerves, "the very ſpecious arguments of my learned colleague (Sauſſure,) in his hygrometry in favour of that opinion, had long ſeduced me; but the charming ſimplicity which the theory of evaporation would acquire if we could diveſt it of the agency of air; the poſſibility I perceive of reducing the whole to the action of fire; the probability which increaſes with the ſimplicity of every natural hypotheſis, attract me, I confeſs, ſtill more forcibly." Page 222.

In the Philoſ. Tranſac. for 1792, there is an eſſay of De Luc on evaporation. This acute philoſopher diſtinctly maintains that vapour in the air is preciſely the ſame as vapour in vacuo, and in both caſes is formed by the intimate union of fire with water; he denominates it *ſteam*, and ſhews that ſteam in air of any denſity, and ſteam in vacuo, affect the hygrometer alike, provided the ſteam has the ſame temperature and elaſticity, at leaſt within the ordinary range of atmoſpheric temperature. He ſtrengthens his opinion of ſteam in air, and in vacuo being the ſame from the fact that cold is produced, or heat abſorbed, by evaporation in both caſes. From the facts as aſcertained reſpecting ſteam by Mr. Watt and others he juſtly infers, that there is a certain minimum diſtance of the particles of ſteam for each temperature, at which they retain their elaſticity; if they are condenſed by any mechanical force within the limit of this diſtance, they loſe their elaſticity and become water; if not, they retain it, and act as any other permanently elaſtic fluid. In ſpeaking of ſteam in air, he obſerves, "that no mechanical cauſe can produce the decompoſition (condenſation) of that fluid, but by forcing its particles to become nearer each other than the actual temperature can admit, which cannot happen in the atmoſphere, except by the accumulation of ſteam itſelf in ſome part of it." "He concludes that the product of evaporation is always of the ſame nature, namely, an expanſible fluid, which either alone, or mixed with air, affects the manometer by preſſure, and the hygrometer by moiſture, without any difference ariſing from the preſence or abſence of air, at leaſt without any perceived hitherto."

In 1793, Mr. Dalton publiſhed a volume of meteorological eſſays, in which he gives a theory of vapour, very nearly allied to that of De Luc above-mentioned, and to the opinion of Pictet, though he ſeems to have been unacquainted with theſe circumſtances. From the reſults of certain experiments and obſervations he concludes, "that the vapour of water (and probably of moſt other liquids) exiſts at all times in the atmoſphere, and is capable of bearing any known degree of cold without a total condenſation, and that the vapour ſo exiſting is one and the ſame thing as *ſteam* or vapour of 212° or upwards. The idea, therefore, that vapour cannot exiſt in the open atmoſphere under the temperature of 212°, unleſs chemically combined therewith, I conſider as erroneous; it has taken its riſe from a ſuppoſition that *air* preſſing upon vapour condenſes the vapour equally with *vapour* preſſing upon vapour, a ſuppoſition we have no right to aſſume, and which, I apprehend, will plainly appear to be contradictory to reaſon and unwarranted by facts; for, when a particle of vapour exiſts between two particles of air, let their equal and oppoſite preſſures upon it be what they may, they cannot bring it nearer to another particle of vapour, without which no condenſation can take place, all other circumſtances being the ſame; and it has never been proved that the vapour in a receiver from which the air has been exhauſted, is precipitated upon the admiſſion of perfectly dry air. Hence then we ought to conclude, till the contrary can be proved, that the condenſation of vapour expoſed to the common air does not in any manner depend upon the preſſure of the air." Eſſays, p. 201.

In 1802, Mr. Dalton publiſhed, in the fifth vol. of the Mancheſter Memoirs, a ſeries of intereſting eſſays relative to evaporation; he found, 1ſt. The expanſive force of pure ſteam over water in vacuo at all temperatures from 32° to 212°; 2d. The expanſive force of dry air for the ſame range of temperature; and, 3d. The expanſive force of dry air in contact with water for the like range. From a compariſion of theſe experiments it appeared that the obſervation of De Luc was univerſally true; namely, that ſteam in vacuo and ſteam in air are preciſely of the ſame force at the ſame temperature. The law was found to apply equally to the ſteam from ether and other liquids, and to other elaſtic fluids, as well as common air. Mr. Dalton conſiders theſe facts to be deciſive as to the nature of the connection between ſteam and air, and infers that ſteam forms a mechanical mixture with air, and not a chemical compound, as ſome have ſuppoſed. This concluſion was confirmed by experiments upon the quantity of water evaporated at different temperatures; which was always is proportion to the elaſtic force of vapour at the temperature. For inſtance, water at 212°, or kept juſt boiling, evaporates twice as faſt as water of 180°, and this twice as faſt as water of 150°; and the forces of pure ſteam at thoſe temperatures are 30, 15, and $7\frac{1}{2}$ inches of mercury reſpectively. The rule, however, does not apply without a correction for low temperatures; becauſe the ſteam already in the air prevents in degree the aſcenſion of freſh ſteam; whereas in high temperatures, the ſmall portion of ſteam commonly in the air is too trifling to have any obſervable effect. Mr. Dalton has given a table founded upon experience, and adapted to the above-mentioned law, by which not only the actual quantity of water evaporated in atmoſpheric temperatures may be aſcertained, but alſo the quantity of vapour exiſting in the air may be found, provided the rate of evaporation is given. The following is an abſtract of it.

The firſt column of the table expreſſes the temperature; the ſecond, the correſponding force of vapour in vacuo, derived from experiment; the third column expreſſes the number of grains of water evaporated per minute, from a ſurface of $28\frac{1}{4}$ ſquare inches, in a moderate current of air or nearly calm; the fourth is the like evaporation in a medium current; and the fifth is the evaporation when a ſtrong breeze exiſts, or a rapid current of air ſweeps over the evaporating ſurface. The air is ſuppoſed to be perfectly dry or free from vapour; otherwiſe every particular ſtate of atmoſpheric vapour would require a table. The table is intended to be uſed when we want to find the quantity of water evaporated from a given ſurface by the ſlow and gradual operation of the atmoſpheric temperature, or what has been called *ſpontaneous* evaporation. But as it is adapted to air perfectly free from vapour, it cannot be of any practical utility without further data. The force of vapour actually exiſting in the atmoſphere at the time muſt be firſt aſcertained, by determining the temperature at which dew begins to be formed on a glaſs, &c. containing cold water or a cold mixture. Then the force due to that temperature muſt always be ſubtracted from the whole force due to the given temperature of the evaporating water.

TABLE.

Temperature	Force of vapour in Inch. of Mer.	Grains of Water evaporated.		
		Loweſt	Mean	Higheſt
212°	30.00	120	154	189
20°	.129	.52	.67	.82
25	.156	.62	.79	.97
30	.186	.74	.95	1.17
35	.221	.80	1.14	1.39
40	.263	1.05	1.35	1.65
45	.316	1.26	1.62	1.99
50	.375	1.50	1.92	2.36
55	.443	1.77	2.28	2.78
60	.524	2.10	2.70	3.30
65	.616	2.46	3.16	3.87
70	.721	2.88	3.70	4.53
75	.851	3.40	4.37	5.34
80	1.000	4.00	5.14	6.29
85	1.17	4.68	6.07	7.46

Problem 1.—Having given the quantity of force of atmoſpheric vapour, to find the rate of evaporation,—

Suppoſe that atmoſpheric vapour begins to be condenſed at 50°, and the temperature of the air is 60°; query the rate of evaporation, with a medium breeze?

Whole evaporating force, per table, for 60° = 2.70 grains.
Exiſting force of atmoſpheric vapour for 50° = 1.92 grains.
Remainder - - .78 grains.

Hence a ſurface of $28\frac{1}{4}$ inches would loſe $\frac{78}{100}$dths of a grain in each minute.

Again; ſuppoſe the atmoſpheric vapour to be at 20°, with a ſtrong breeze, in one caſe, the air being 32°; and the atmoſpheric vapour to be at 50°, in another caſe, with calm air at 58°; query the rates of evaporation in thoſe two caſes?

1ſt Caſe. Whole evaporating force per table, for 32° - - - = 1.26 grains.
Exiſting force of atmoſ. vap. for 20° = .82 grains.
Remainder, or rate of evaporation = .44 grains.

2d Caſe. Whole evaporating force, per table, for 58° - - - = 1.96 grains.
Exiſting force of atmoſ. vap. for 50° = 1.50 grains.
Remainder, or rate of evaporation = .46 grains.

Hence it appears that under the circumſtances above-mentioned the evaporation would be nearly the ſame in both caſes.

Problem 2.—Having given the rate of evaporation, to find the quantity or force of amoſpheric vapour.

Suppoſe the evaporation from a ſurface of $28\frac{1}{4}$ inches is found to be one grain in a minute, with a medium breeze, the temperature being 70°; query the quantity and force of atmoſpheric vapour?

Whole evaporating force, per table, at 70° = 3.70 grains.
Obſerved evaporating force - - = 1.00 grains.
Remainder = exiſting atmoſpheric force 2.70 grains,

which correſponds to 60°, for the temperature at which the atmoſpheric vapour would be found to be condenſed at the time.

Mr. Dalton contends that all the different gaſes conſtituting the atmoſphere, namely, azotic, oxygenous, carbonic acid, and ſteam, are independent of each other; ſo that they preſs the ſurface of the earth and other bodies with their own weight only, when in a ſtate of equilibrium. Whence he conſiders the *quantity* and *force* of ſteam in the atmoſphere as ſynonymous terms. Thus in the above example, the force of ſteam of 60° being repreſented by .524 parts of an inch of mercury, the weight of the incumbent atmoſphere of ſteam muſt be the ſame, or equal to 7 inches of water nearly. This notion, concerning the whole quantity of ſteam in the atmoſphere incumbent upon any place, is entirely new; and, if correct, muſt be of the firſt importance in meteorology.

Though the reaſons aſſigned by De Luc and Dalton for the non-condenſation of ſteam, already exiſting in air, appear to be incontrovertible, yet from what has been ſaid above, no ſufficient reaſon has been given by either of them for the *entrance* of ſteam of low temperatures into the atmoſphere. How does ſteam of $\frac{1}{60}$th part of the force of the atmoſphere at firſt penetrate it? Even Sauſſure ſpeaks of the fact, and as if there were no difficulty attending it. De Luc does not attempt any explanation. Dalton ſeems to have been fully aware that the hypotheſis of pure ſteam exiſting in air was not tenable without obviating this difficulty. Accordingly he conceived that the particles of ſteam are not repulſive to thoſe of air, but only to other particles of ſteam; hence the new formed ſteam has a kind of vacuum, to enter in the pores or interſtices of the air. But this, it is thought by many, is going into the other extreme, and making the facility much too great; beſides, there is no notion ſo general and ſo probable, as the one that heat is the cauſe of repulſion; and if this notion be true, the particles of ſteam cannot be admitted to be repulſive of each other, and indifferent to thoſe of air. Mr. Dalton, it ſeems, now conſiders the inequality in the ſize of the ultimate particles of different elaſtic fluids to be the cauſe why they are conſtantly diffuſing themſelves through each other, and never obtain a proper equilibrium till their particles take the arrangement, which they would do in a vacuum; and the elevation of ſteam from the ſurface of water, he ſuppoſes, takes place, becauſe certain particles of the ſurface are in a great meaſure exempt from the preſſure of the atmoſphere. See New Syſtem of Chemical Philoſophy, p. 190.

From the experiments of Mr. Watt on ſteam, it appears that evaporation at high and low temperatures is much the ſame as to the expenditure of heat for a given weight of water.

The evaporation from ice of 32° does not differ materially from that of water, at the ſame temperature. Electricity is ſaid to promote evaporation in ſome degree.

Evaporation in Meteorology.—With reſpect to the natural evaporation of water from the ſurface of the earth, the experiments of Mr. Hoyle and Mr. Dalton, of Mancheſter, are nearly the only ones that are ſufficiently numerous from which to draw any concluſions. They took a cylindrical veſſel of tinned iron, 10 inches in diameter, and three feet deep; there were two pipes ſoldered into it, one at the bottom, the other at the top, for the water to run off into bottles. The veſſel was filled with gravel, ſand, and ſoil, and ſubſequently the ſoil was covered with graſs and other living vegetables. It was nearly buried in the ground in an open ſituation, and proviſion made for placing bottles to the two pipes. In this manner it was expoſed to receive the rain, and to ſuffer evaporation from the ſurface, the ſame as the ſurrounding green ground. A regular regiſter was kept of the water which percolated through the ſoil and gravel into the bottles; and a rain gage of the ſame ſurface was kept cloſe by, for the ſake of compariſon. The reſults are contained in the table below, together with the mean evaporation from a like ſurface of water, for the three ſucceeding years.

Water through the two Pipes.							
	1796	1697	1798	Mean.	Mean Rain.	Mean Evap. from Ground	Mean Evap. from Water.
	Inch.	Inch.	Inch.	Inch.	Inch.	Inch.	Inch.
January	1.90	.68	1.77	1.45	2.46	1.01	1.50
February	1.78	.92	1.12	1.27	1.80	.53	2.00
March	.43	.07	.34	.28	.90	.62	3.50
April	.22	.30	.18	.23	1.72	1.49	4.50
May	2.03	2.44	.01	1.49	4.18	2.69	4.96
June	.17	.73	—	.30	2.48	2.18	6.49
July	.15	03	—	.06	4.15	4.09	5.63
Auguſt	—	—	.50	.17	3.55	3.38	6.06
September	—	.98	—	.33	3.28	2.95	3.90
October	—	.68	—	.23	2.90	2.67	2.35
November	—	1.04	1.59	.88	2.93	2.05	2.04
December	.20	3.08	1.88	1.72	3.20	1.48	1.50
	6.88	10.95	7.39	8.41	33.55	25.14	44.43
Rain	30.63	38.79	31.26				
Evap.	23.75	27.84	23.87				

From this table it appears that the evaporation from a ſurface of water, is nearly twice as much as from green ground; alſo, that about eight or nine inches of rain are left for the ſupply of ſprings and rivers. This ſurplus of water muſt be evaporated from the ſea, and return to it again by the rivers.

Evaporation in Chemiſtry.—When artificial heat is applied, the quantity evaporated will be nearly in geometrical progreſſion to the exceſs of temperature, above that of the air. It is always nearly in proportion to the ſurface expoſed. When the liquid is much below the margin of the veſſel, the evaporation is greatly retarded.

Evaporation in the Arts. In certain arts, ſuch as dyeing, printing, &c. quick evaporation is expedient. This is effected by expoſing the wet pieces in a ſtove, which has commonly a fire and long flues from which the heat is diſſipated into the room. The cold air ſhould be admitted into the room as near the fire and flues as poſſible; and ſeveral ſmall openings at the top of the ſtove ſhould be made to ſuffer the vapoury air to eſcape.

See the articles CLOUDS, DEW, DISTILLATION, HYGROMETER, RAIN, STEAM, &c.

EVAPORATION, in *Pharmacy*, *Chemiſtry*, &c. denotes an operation by which the more aqueous and volatile parts of fluids are ſpent, or driven away in ſteam, ſo as to leave the remaining part ſtronger, or of a higher conſiſtence than before.

Evaporation is effected by ſetting a liquor over a gentle heat, to carry off the moſt fluid and volatile parts, without leſſening the quantity of the other matters with which the liquor is impregnated.

The veſſels uſed for this purpoſe are baſons, teſts, or crucibles, which are made of glaſs, metal, or earth, according to the nature of the bodies on which the operation is to be performed. They are flat, ſhallow, and wide, ſo that the body from which the evaporation is to be made may preſent a large ſurface to the air. In all evaporations the degree of heat ought to be proportioned to the volatility of the ſubſtance to be evaporated, and to the degree of fixity of the ſubſtance intended to be left, and of its adheſion to the volatile parts. In ſome caſes, as in obtaining oil from rectified ſpirit of wine and ether, the liquors ought to be evaporated upon the ſurface of water in open air, without any other heat than that of the atmoſphere; in others, when the part to be evaporated is not very volatile, and when the remaining ſubſtance is very fixed, and does not adhere much to the volatile part, as in the purification of gold by antimony, a ſtrong heat may be applied, and a current of air directed upon the ſurface of the body. Macquer.

EVARCHUS, in *Ancient Geography*, a river of Aſia, forming the boundary between Paphlagonia and Cappadocia. Valerius Flaccus aſſigns it to Scythia, and ſays it abounded with ſwans.

EVARISTUS, in *Biography*, biſhop of Rome, was elected to that office about the year 100, in which he continued eight or nine years. Much has been ſaid of him with regard to his decretals; his diſtribution of Rome into pariſhes, his preſenting Adrian with a book concerning the excellence of the Chriſtian religion, and his martyrdom under the reign of that emperor; but theſe and other facts collected by modern writers do not ſtand on ſufficient authority to obtain credit. Moreri.

EVASION, EVASIO, in *Law*, is uſed for any ſubtile endeavour to ſet aſide truth, or to eſcape the puniſhment of the law, which will not be endured. Thus, if a perſon ſays to another that he will not ſtrike him, but will give him a pot of ale to ſtrike him firſt; and accordingly he ſtrikes, the returning of it is puniſhable; and if the perſon firſt ſtriking be killed, it is murder; for no man ſhall evade the juſtice of the law by ſuch a pretence to cover his malice. 1 Hawk. P. C. 81.

EUASPLA, in *Geography*, a river of India, in the northern part of the mountain Paropamiſus, which ran S.E. into the Indus.

EVATES, a branch or diviſion of the ancient Celtic philoſophers, the Druids.

Strabo diſtributes the philoſophers among the Britons and Gauls into three ſects; Βαρδοι, *Bards*, Ουατεις, *Evates*, and Δρυιδαι, *Druids*. He adds, that the Bards were poets and muſicians; the Evates, prieſts and naturaliſts; and the Druids, moraliſts as well as naturaliſts. But Marcellinus, Voſſius, and Hornius, reduce them all to two ſects, *viz.* Bards and Druids. Laſtly, Cæſar, lib. vi. comprehends them all under the name of *Druids*; which ſee.

The Evates or Vates of Strabo might probably be what other authors, and particularly Ammian. Marcellin. calls *Eubages*; but Mr. Bouche, in his Hiſt. de Provence, lib. ii. chap. 2. diſtinguiſhes between them. The Vates, he ſays, were ſuch as took care of the ſacrifices and other ceremonies of religion; and the Eubages, thoſe who ſpent their time in the ſearch and contemplation of the great myſteries of nature.

EVAUX, in *Geography*, a town of France, in the department of Creuſe, and chief place of a canton, in the diſtrict of Aubuſſon; 26 miles E. of Gueret. The number of inhabitants in the place is 2,081, and in the canton 8,036, and the territorial extent of 232½ kiliometres includes 12 communes. Near it are a mineral ſpring and baths. N. lat. 46° 10′. E. long. 3° 33′.

EVAX, in *Botany*, Gærtn. v. 2. 393, ſee Filago.

EVAZA, in *Ancient Geography*, an epiſcopal ſee of Aſia propria, under the metropolis of Epheſus; mentioned in the acts of the council of Epheſus.

EUBAGES, an order of prieſts or philoſophers among the ancient Celtæ or Gauls. Chorier takes the Eubages to be the ſame with the Druids and Saronidæ of Diodorus. Others will have the Eubages to be thoſe whom Strabo, lib. iv. p. 197. calls Ουατεις, *Evates*, or *Vates*, on which principle there is room to conjecture, that the word ſhould be written Ουαγεις, it being eaſy to miſtake a Γ for a T. See Druid.

EUBELSTADT, in *Geography*, a town of Germany, in the biſhopric of Wurzburg, on the Maine; three miles S. of Wurzburg.

EUBŒA, in *Ancient Geography*, one of the moſt conſiderable of the Greek iſlands, formerly joined to Bœotia, as Pliny informs us, by an iſthmus, ſo narrow is the Euripus in ſome places, which ſeparates it from the continent; and extending from north-eaſt to ſouth-weſt 150 miles; but where broadeſt being only 40 miles, and 20 where it is narroweſt. In compaſs it is eſtimated at 365 miles. This iſland was anciently denominated Chalcis, Ellopia, Aonia, Abantis or Abantia, Macris, Oche, Bomo, &c. Its appellation Eubœa is ſaid to be derived from a famous cave on the eaſtern coaſt of the iſland, called by the Greeks αυλη βοος, or the ox ſtall, and this name was probably deduced from its excellent paſtures. Eubœa had ſeveral remarkable promontories, which ſtretched far into the ſea; of theſe Pliny and Mela mention three, *viz.* Geraſtus and Caphareus to the ſouth, and Cenæum to the north; and Strabo mentions a fourth, which he calls Petalia, over-againſt Sunium. Cenæum, now Capo Liter, and Geraſtus, now Capo Roſſo, are, according to Strabo, 1200 furlongs diſtant from each other, which meaſure exactly the length of the iſland, as it is ſet down by Pliny. The mountains of Eubœa are high, and covered during a great part of the year with ſnow. The famous city of Chalcis was ſituated under one of them of the ſame name, and on another, called Dryphis, was a temple dedicated to Diana. The following rivers are mentioned by Strabo, *viz.* Callas, Budarus, Cireczus, and Neleus or Melas. The champaign country was exceedingly fertile, and yielded great plenty of corn, wine, oil, and all ſorts of delicious fruits; but it was chiefly famous for its rich paſtures. This iſland had in former times many cities of great note, which are mentioned by Strabo, Pliny, Ptolemy, and Mela. On the eaſtern coaſt ſtood the cities of Geraſtus, which was a famous haven, Petalia, and Caryſtus, near which were the celebrated quarries of Caryſtian marble, ſo much valued by the Romans, and alſo of Amianthus or Aſbeſtos. About five miles from Caryſtus was the village of Amarynthus, famous for a temple of Diana. On the ſame coaſt ſtood Eretria and Chalcis, which ſee reſpectively. Between Chalcis and the promontory Cenæum, ſtood the cities of Edepſum and Oreos; the former being famous for its hot-baths, and the latter one of the moſt powerful cities of Eubœa during the Trojan war, and occupying the fourth part of the iſland, in the time of Philip, the father of Alexander. The name Oreos was changed by the Athenians, when they became maſters of the iſland by means of Pericles, into that of Iſtiæa, or Heſtiæa, which was the name of their tribe. On the north ſide of the iſland, oppoſite Theſſaly, and extending from Cenæum to Artemiſium, ſtood Dia, or Athenæ Diades; and on the coaſt, waſhed by the Ægean ſea, ſtood the maritime city of Cerinthus. The inland cities mentioned by Strabo, Pliny, Ptolemy, &c. were Ellopia, Nyſa, Eubœa, Orabiæ, Rhamnus, Porthmus, Algæ, and Tamyna.

Eubœa was probably one of the iſlands in which the firſt Orientals, who paſſed from the continent of Aſia towards the coaſts of Greece, made a ſettlement. It muſt have formed a very powerful ſtate at an early period, ſince its king Elephenor conducted 40 ſhips to the war of Troy. Solinus aſcribes the commencement of this monarchy to the Titans. Others ſuppoſe Abas to have been the firſt ſovereign of Eubœa. The ſucceſſion of its ſovereigns is little known. In the time of Darius Hyſtaſpis, the cities of Chalcis, Eretria, Caryſtus, and Oreos, formed diſtinct republics, governed by the nobles, whom they called hippobates, or horſemen; none being received into the government who were not able to maintain a certain number of horſes. This oligarchy was not of long duration; but it was ſucceeded by a democracy, compoſed of domeſtic tyrants, who ſeized all power to themſelves, and ruled in their ſeveral cities without controul. At length the Eubœans ſubmitted firſt to Philip of Macedon, and then to his ſon Alexander, on whoſe death they endeavoured to ſhake off the Macedonian yoke; but they were again brought under ſubjection by Antigonus. When the Romans firſt paſſed into Greece, the kings of Macedon held this iſland in ſubjection; but it was ſoon after declared free by the ſenate, in order to weaken the power of Philip in theſe parts. But not being ſupplied with forces, they were unable to maintain their liberty; and fell under the power of Antiochus the Great, and Mithridates king of Pontus. The Romans, however, prevailing in the Eaſt, reſtored the Eubœans to their former ſtate of liberty. It was not long before Marc Antony ſubjected them to Athens; but Auguſtus, incenſed againſt the Athenians for aſſiſting his rival, firſt gave freedom to the city of Eretria, and ſoon after to the whole iſland, which remained in a flouriſhing condition, under its own laws, till the reign of Veſpaſian, when it underwent the ſame fate as the other ſtates of Greece.

Eubœa, the name of ſeveral towns in the iſland of Eubœa, Corcyra, and Lemnos.

EUBULIDES, in *Biography*, a native of Miletus, was a ſucceſſor of Euclid in the Megaric ſchool. He was a ſtrong opponent of Ariſtotle, and ſeized every occaſion of cenſuring his writings and calumniating his character. He introduced new ſubtleties into the art of diſputation, ſeveral of which, though often mentioned as proofs of great ingenuity, deſerve only to be remembered as examples of egregious trifling. They belong to that ſophiſtical mode of reaſoning, called by Ariſtotle eriſtic ſyllogiſms. A ſingle ſpecimen will be ſufficient. It ſhall be of the ſophiſm, called from the example, "the Lying:" if, when you ſpeak the truth, you ſay you lie, you lie; but you ſay you lie, when you ſpeak the truth; therefore in ſpeaking the truth, you lie. Theſe ſilly inventions for perplexing plain truth were formerly in ſuch high repute, that Chryſippus wrote ſix books upon the above mentioned ſophiſm; and Philetas, a Choan, died of a conſumption which he contracted by the cloſe ſtudy he beſtowed upon it. The inſcription upon his tomb was Ὁ ψευδόμενος, "The Deceived." Brucker's Hiſt. Phil. by Enfield, vol. i. p. 192.

EUCALYPTUS, in *Botany*, from ευ, *well*, and καλυπτος, *covered*, alluding to the peculiar lid which covers the calyx and encloſes the organs of impregnation. L'Herit. Sert. Angl. 18. Ait. Hort. Kew. v. 2. 157. Willd. Sp. Pl. v. 2. 976. Mart. Mill. Dict. v. 2. Sm. Bot. of N. Holl. 39. Juſſ. 451. Claſs and order, *Icoſandria Monogynia*. Nat. Ord. *Heſperideæ*, Linn. *Myrti*, Juſſ.

Gen. Ch. *Cal.* Perianth ſuperior, of one leaf, abrupt, entire, permanent, cloſed before impregnation with a convex or conical, entire, deciduous lid, which is ſometimes, if not always, of two or three layers. *Cor.* none. *Stam.* Filaments numerous, thread-ſhaped, equal, inſerted into the margin of the calyx within the lid, and not expanding till after it falls, anthers roundiſh, two-lobed, ſmall. *Piſt.* Germen inferior, urceolate, firmly united with the baſe of the calyx, ſometimes angular; ſtyle ſimple, columnar, about as long as the full-grown ſtamens; ſtigma ſimple, bluntiſh. *Peric.* Capſule roundiſh, crowned with the rim of the calyx, of three or four cells, opening at the top. *Seeds* numerous, angular, ſmall.

Eſſ. Ch. Calyx ſuperior, permanent, truncated, covered before flowering with an entire lid, which ſoon falls off. Capſule of three or four cells, opening at the top. Seeds numerous.

This genus was founded by the late M. L'Heritier in his Sertum Anglicum, upon a ſingle ſpecies, from Van Diemen's land, named by him *obliqua*, and figured in the 20th plate of that work. Its deſcription never appeared. The generic characters were by him communicated to the Hortus Kewenſis, and adopted, with ſome neceſſary corrections, in Dr. Smith's Botany of New Holland, where a ſecond ſpecies is figured, *E. robuſta*, t. 13. This is called New Holland Mahogany, or Brown Gum Tree, and is one of the lofticſt trees about Port Jackſon, being often 100 feet high, and proportionably thick. The wood hard, heavy, ſtrong, red and very reſinous. *Leaves* alternate, ſtalked, ovate, entire, a little oblique and unequal. *Flowers* in denſe ſimple umbels, of a tawny yellow, on ſimple or divided angular ſtalks, growing in a corymboſe manner about the ends of the branches. The *lid* in this ſpecies is conical, as long as the calyx and germen, with a ſtricture in the middle; that of the former is ſhort and hemiſpherical, with a minute point. Four more ſpecies from New South Wales are deſcribed in the work laſt mentioned, and ſix additional ones by the ſame author in the Tranſ. of the Linn. Soc. v. 3. p. 283—288. All theſe 12 are adopted by Willdenow in his Sp. Pl. A new one, *E. marginata*, was added to this liſt by Dr. Smith in Tr. of Linn. Soc. v. 6. 302, who has ſince figured and fully deſcribed one of the moſt important of the former, *E. reſinifera*, the Red Gum Tree, in his Exotic Botany, v. 2. 49. t. 84. This bloſſomed in Lady De Clifford's greenhouſe at Paddington. The *flowers* are green with white ſtamens. *Lid* conical, twice as long as the calyx and germen, conſiſting of three coats, of which the outermoſt is formed of three ribs originating from the angles of the germen.—The tree produces an aſtringent reſin of a fine deep red, whoſe probable uſes in medicine or the arts merit enquiry. Many more ſpecies of this genus are ſaid to abound in New Holland, all lofty trees, deſtitute of hairineſs, with ſimple, lanceolate, or ſomewhat ovate, pointed, entire leaves, generally oblique, and often unequal, at the baſe; without ſtipulas. They are commodiouſly divided into two ſections, by their hemiſpherical or conical lids.

EUCARPIA, in *Ancient Geography*, a town of Aſia, in Greater Phrygia, according to Ptolemy and Strabo.

EUCERA, in *Entomology*, a genus of Hymenoptera, propoſed by Scopoli, and adopted by various late writers. Under this denomination are comprehended thoſe of the Linnæan genus Apis (bee), which have the mandibles horny, incurvated, acute, and toothleſs; jaw elongated, and membranaceous at the tip; lip horny, five-cleft; tongue inflected and ſeven-cleft; antennæ cylindrical, thoſe of the male very long, and often exceeding the length of the body; the abdomen ſhort and downy; tail of the female armed with a ſting. The inſects of this genus form cylindrical cavities in the earth, in which they depoſit their eggs, each included in a ſeparate cell, and furniſhed with a ſuitable proviſion of honey for the ſubſiſtence of the young when hatched. In the winged ſtate the Euceræ fly with great rapidity, and like the bee, collect the farina and nectar of flowers with great induſtry and activity. The females commonly differ much in appearance from the males of the ſame ſpecies, independently of the length of the antennæ.

Species.

Longicornis. Black; ſummit of the head, thorax, and two firſt rings of the abdomen above grey-downy; reſt of the abdomen nearly glabrous. Latreille. *Eucera longicornis*, Fabr. Kirby. Ap. Angl.

Native of Europe. The female of this ſpecies is not diſtinctly aſcertained. Mr. Kirby ſeems to entertain no doubt of its being the inſect figured by Panzer under the name of Andrena ſtrigoſa. Since his obſervations appeared, however, Latreille has written on the ſame ſubject, and though he does not refer to the remark of Mr. Kirby, he evidently alludes to it in the following paſſage, "Je doute que l'andrene, que Panzer nomme *ſtrigoſa*, ſoit la femelle de cette eſpèce. Son abdomen eſt très-différent par ſes taches de celui de *l'eucere longicorne* et cet inſecte ne paroît qu'au milieu du l'ete, tandis que le dernier ne ſe voit, qu'au printemps." The difference of the abdomen may perhaps be conſidered in this ambiguous race leſs definitive than the time of its appearance in the winged ſtate; for if the firſt be conſtantly found only in the middle of the ſummer, and the other in ſpring, we ſhould admit them to be diſtinct. It further merits obſervation that Latreille deſcribes an inſect which he imagines to be the true female, "La femelle, &c."—"The female, or, at leaſt, that which I regard as ſuch, and of which I have ſeen an individual in the collection of the naturaliſt Baumhaaver, differs only in the ſhortneſs of the antennæ; the head entirely black, and the poſterior feet very downy." The ſpecies inhabits Europe.

Atricornis. Antennæ black, as long as the body, which is hairy and ferruginous. Fabr.

Native of Barbary.

Glauca. Antennæ ferruginous, as long as the body, the latter hairy and glaucous. Fabr. Sp. Inſ. &c.

Inhabits the Eaſt; two firſt ſegments of the abdomen with a black band.

Linguaria. Antennæ black, length of the abdomen; thorax cinereous; abdomen black. Fabr.

Native of Europe, on flowers.

Tumulorum. Antennæ length of the abdomen; body black; legs and jaws yellowiſh. Linn. Fn. Suec. *Eucera tumulorum*, Fabr.

An European inſect, alſo found on flowers.

Griſescens. Antennæ black, as long as the body; the latter hairy and cinereous. Fabr.

Inhabits Barbary.

Antennata. Antennæ as long as the body; abdomen black, with whitiſh ſtreaks. Fabr.

A ſmall inſect, found in abundance in the environs of Paris in autumn, and alſo in other parts of Europe. The lip is marked with a trilobate ſpot of yellow; the head and thorax cinereous; abdomen glabrous; edges of the ſegments fringed with white, legs teſtaceous.

Curvicornis. Blackiſh-grey; antennæ convoluted, ſub-clavated; abdomen roundiſh; margin of the wings black. Scopoli. Native of Carniola.

Brevicornis. Ferruginous hairy; abdomen braſſy; antennæ ſhort and black. Fabr. Suppl.

This is an inhabitant of Italy, and is deſcribed by Fabricius from the cabinet of Dr. Allioni. The head, thorax, and legs with ferruginous hairs.

Craſſipes. Hairy cinereous; abdomen black, with the margins of the ſegments greeniſh; poſterior thighs thick. Fabr. Suppl.

Native of Tranquebar in the cabinet of Lund. The antennæ of this inſect are ſhort; the wings are duſky with fuſcous tip; legs yellowiſh; thighs of the poſterior pair thick, dentated, and black; ſhanks incurvated, toothed, and yellow. Whether this and the ſpecies immediately preceding ought ſtrictly to be placed with the Euceræ, (ſo named from the length of their antennæ,) if they ſhould be of the male kind, may be ſubmitted with deference; the ſex is not mentioned in either inſtance. Fabricius deſcribed them as Euceræ, and they agree in every reſpect with that genus, except in the remarkable brevity of the antennæ.

EUCHARIST, Euchariſtia, the ſacrament of the Supper, or a participation of the body and blood of Chriſt, under the ſpecies or figures of bread and wine. See Communion, Sacrament, Species, Tranſubſtantiation, and Conſubſtantiation.

The word in its original Greek, Ευχαριϛια, literally imports *thankſgiving*, being formed of ευ, *bene*, *well*, and χαρις, *gratia*, *thanks*.

EUCHENDORF, in *Geography*, a town of Lower Bavaria, on the Vils; 14 miles W. of Vilzhofen.

EUCHERIUS, in *Biography*, a biſhop of Lyons in the fifth century, began his career in ſecular life, in the various offices of which he acquired wealth. He ſuſtained the rank of ſenator, and having married, had ſeveral children, among whom were two ſons, whom he lived to ſee advanced to the epiſcopal dignity. Wearied with the purſuits of the world, he embraced a monaſtic life, which he quitted for the biſhopric of Lyons in the year 434. He attended the deliberations of the firſt council of Orleans in the year 441, and was diſtinguiſhed for his learning and ſagacity. He was a popular preacher, upon thoſe principles of grace which were vindicated by St. Auguſtine. He died about the year 454. Among the various pieces attributed to Eucherius, may be noted "Epiſtola de Laude Eremi, ſeu de Vita Solitaria," intended to extol the advantages of aſcetic life, written, for the times, with uncommon beauty and purity of language: "Epiſtola Parænetica de contemptu Mundi, et Sæcularis Philoſophiæ ad Valerianum Cognatum ſuum," which was publiſhed by Eraſmns, with annotations, at Baſil in the year 1520, and pronounced to be one of the moſt elegant pieces of antiquity. To theſe may be added two treatiſes intended to illuſtrate difficult paſſages of Scripture, of leſs value than thoſe mentioned above. Theſe, and ſome others attributed to Eucherius, were collected and publiſhed at Baſil in 1531, at Rome in 1564, and are likewiſe to be found in the ſixth volume of the "Bibliotheca Patrum." There was another Eucherius who was likewiſe a biſhop of Lyons, and aſſiſted at the ſecond council of Orleans about the year 529. Moreri.

EUCHITES, or Euchitæ, in *Eccleſiaſtical Hiſtory*, a ſect of ancient heretics, who were firſt formed into a religious body towards the end of the fourth century, though their doctrine and diſcipline ſubſiſted in Syria, Egypt, and other eaſtern countries before the birth of Chriſt; they were thus called becauſe they prayed without ceaſing, imagining that prayer alone was ſufficient to ſave them.

Their great foundation was thoſe words of St. Paul, Epiſt. i. to the Theſſalonians, chap. v. ver. 17. *pray without ceaſing.*

The word is formed of the Greek, ευχη, *prayer*, whence ευχιται, the ſame with the Latin, *precatores*, *prayers*. They were alſo called *Enthuſiaſts* and *Maſſalians*, a term of Hebrew origin, denoting the ſame as Euchites.

The Euchites were a ſort of myſtics who imagined, according to the oriental notion, that two ſouls reſided in man, the one good and the other evil; and who were zealous in expelling the evil ſoul or dæmon, and haſtening the return of the good ſpirit of God, by contemplation, prayer, and ſinging of hymns. They alſo embraced the opinions nearly reſembling the Manichean doctrine, and which they derived from the tenets of the oriental philoſophy. The ſame denomination was uſed in the twelfth century, to denote certain fanatics who infeſted the Greek and Eaſtern churches, and who were charged with believing a double Trinity, rejecting wedlock, abſtaining from fleſh, treating with contempt the ſacraments of Baptiſm and the Lord's Supper, and the various branches of external worſhip, and placing the eſſence of religion ſolely in external prayer, and maintaining the efficacy of perpetual ſupplications to the Supreme Being for expelling an evil being or genius, which dwelt in the breaſt of every mortal. This ſect is ſaid to have been founded by a perſon called Lucopetrus, whoſe chief diſciple was named Tychicus. By degrees it became a general and invidious appellation for perſons of eminent piety and zeal for genuine Chriſtianity, who oppoſed the vicious practices and inſolent tyranny of the prieſthood; much in the ſame manner as the Latins comprehended all the adverſaries of the Roman pontiff under the general terms of *Waldenſes* and *Albigenſes*. Moſh. Eccl. Hiſt. Eng. edit. 8vo. vol. i. p. 350. and vol. ii. p. 441.

St. Cyril of Alexandria, in one of his letters, takes occaſion to cenſure ſeveral monks in Egypt, who, under pretence of reſigning themſelves wholly to prayer, led a lazy, ſcandalous life. A cenſure likewiſe applicable to monaſteries in general.

EUCHOLOGIUM, Ευχολογιον, a Greek term, ſignifying, literally, *a diſcourſe on prayer.*

The word is formed of ευχη, *prayer*, and λογος, *diſcourſe.*

The Euchologium is properly the Greek ritual, wherein are preſcribed the order and manner of every thing relating to the order and adminiſtration of their ceremonies, ſacraments, ordinations, &c.

Fa. Goaar has given us an edition of the Greek Euchologium in Greek and Latin, with notes, at Paris.

EUCHROON, in *Surgery*, a plaſter mentioned by Scribonius Largus.

EUCHYMIA, from ευ, *good*, and χυμος, *juice*, in *Medicine*, a good temper of the blood, or other juices and fluids in an animal body.

EUCLABRIS, in *Antiquity*, a table whereon the ſlaughtered victim was ſpread, in order to have its inteſtines carefully inſpected. It was from this table that the veſſels uſed in ſacrifices were called *euclabria.*

EUCLASE. The colour of this mineral is a very clear ſea-green. It occurs only cryſtallized. Its primitive form is that of an oblique quadrilateral priſm, but its ſummits are generally ſo complicated by truncatures and bevellings as to render a mere verbal deſcription of it wholly unintelligible: in this ſtate it reſembles certain varieties of topaz, but may readily be diſtinguiſhed by meaſuring the obtuſe angles of the priſm, which in this mineral are 133°, whereas in the topaz they are 124°; its lamellæ alſo are not perpendicular to the axis of the priſm. It has a brilliant vitreous luſtre. Its fracture in the direction of its axis and parallel to the ſmall diagonal of its baſe is perfectly lamellar; but when parallel to the large diagonal is very imperfectly ſo. Its croſs fracture is ſomewhat conchoidal. It is tranſparent and has a double refraction. It is ſufficiently hard to ſcratch quartz, but is remarkably brittle. Sp. gr. = 3.06.

When expoſed to the blowpipe, it firſt loſes its tranſparency, and then melts into a white enamel. It has been analyſed by Vauquelin, with the following reſult:

Silex	35 to 36
Alumine	18 — 19
Glycine	14 — 15
Iron	2 — 3
	69 — 73
Loſs	31 — 27
	100 — 100

This mineral is ſo very rare that only a ſmall portion could be afforded for analyſis; of the loſs, Vauquelin attributes the greateſt part to water of cryſtallization, and the reſt is probably alkali.

The euclaſe was found in Peru by Dombey, and all the ſpecimens in the cabinets of Europe were brought over by this naturaliſt.

EUCLEA, in *Botany*, is derived by Profeſſor Martyn from ευκλεια, *glory*, or *celebrity*, which ſeems in no reſpect applicable to this plant. We would rather explain it by ευ, *well*, and κλειω, *to ſhut up*, becauſe of the manifold coverings of the ſeeds, each of which is encloſed in an arillus, within the cell of a capſule, whoſe outſide moreover is protected with a covering of pulp. To all this indeed L'Heritier firſt adverted, and not Linnæus nor Thunberg, one of whom probably invented the name. Linn. Suppl. 67. Thunb. Nov. Gen. 84. L'Herit. Sert. Angl. 31. Schreb. 699, 700. Juſſ. 432. Claſs and order, *Dioecia Dodecandria*, or perhaps, as the Linnæan Syſtem now ſtands, *Polygamia Monoecia.* Nat. Ord. uncertain, Juſſ.

Gen. Ch. *Cal.* Perianth inferior, ſmall, with five teeth, permanent. *Cor.* of one petal, larger than the calyx, in five deep, ovate, obtuſe, equal, ſpreading ſegments. *Stam.* Filaments about fifteen, ſhort, inſerted into the receptacle; anthers erect, ſquare, ſlightly downy, ſhorter than the corolla. *Piſt.* Germen ſuperior, ovate, ſomewhat pyramidal; ſtyles two, the length of the ſtamens; ſtigmas ſimple. *Peric.* Capſule with a pulpy coat, roundiſh, with three horns, three cells, and three valves. *Seeds* ſolitary, roundiſh, each encloſed in an arillus; one or two of them frequently proving abortive.

Eſſ. Ch. Calyx with five teeth. Corolla in five deep equal ſegments. Stamens 15. Styles two. Capſule ſuperior, of three cells, pulpy-coated. Seeds ſolitary, encloſed in an arillus.

Obſ. L'Heritier, from whom the above characters are taken, remarks that ſome flowers have an abortive germen, but he never ſaw any that were entirely female without ſtamens. Thunberg deſcribes diſtinct male and female flowers, and aſſerts that the former are moſt frequently five-cleft, the latter four-cleft. Linnæus does not advert to any ſuch difference.

Thunberg defines three ſpecies, all natives of the Cape of Good Hope, in his Prodromus, p. 85.

1. E. *lancea.* "Leaves lanceolate, flat."

2. E. *racemoſa.* "Leaves ovate, flat."—E. racemoſa; Linn. Suppl. 428. L'Herit. Sert. Angl. 32. Ait. H. Kew. v 3. 411. (Padus foliis ſubrotundis, fructu racemoſo; Burm. Afric. 238. t. 84. f. 1: and Euonymus foliis ſubrotundis integris, fructu corniculato; ibid. 260. t. 97. f. 1. E. africanus, foliis laurinis, fructu aculeato; Breyn, Ic. 31. t. 22. f. 3.) A ſmooth branching ſhrub, with alternate, obovate, thick, ſomewhat revolute *leaves*, about an inch long, on ſhort footſtalks. *Flowers* eight or ten in each axillary drooping cluſter, about as long as its correſponding leaf. *Petals* ſnow-white. *Fruit* red, the ſize of a pea.

3. E. *undulata.* "Leaves ovate, undulated."—Much like the laſt in general aſpect. Its red fruit is eaten by the Hottentots, who call the plant Guarri-boſches.

EUCLID, in *Biography*, a native of Megara, and founder of the Megaric or Eriſtic ſect, was diſtinguiſhed by his ſubtle genius, and early application to the ſtudy of philoſophy. Having acquired ſome knowledge of the art of diſputation from the writings of Parmenides, he was induced by the fame of Socrates to remove from Megara to Athens, where he became the auditor and diſciple of this eminent philoſopher. Notwithſtanding the terror of the decree which enacted, that any inhabitant of Megara who ſhould be ſeen at Athens ſhould forfeit his life, he frequently came to Athens by night, from the diſtance of about 20 miles, concealed in a long female cloak and veil, to viſit his maſter. He alſo frequently engaged in the buſineſs and diſputes of the civil courts, by which proceeding he offended Socrates, who deſpiſed forenſic conteſts; and this circumſtance ſeems to have occaſioned a ſeparation between them. Afterwards he put himſelf at the head of a ſchool in Megara, where his chief employment was to teach the art of diſputation. Although he was much addicted to vehement debates, he poſſeſſed ſo great a command of temper, that in a quarrel with his brother, who ſaid to him, "Let me periſh if I be not revenged upon you," Euclid replied, "And let *me* periſh, if I do not ſubdue your reſentment by forbearance, and make you love me as much as ever."

Averſe from the analogical method of reaſoning, Euclid was of opinion that legitimate argumentation conſiſts in deducing fair concluſions from acknowledged premiſes. He held, that there is one ſupreme good, which is called by the different names of Intelligence, Providence, God; and that evil, conſidered as an oppoſite principle to the ſovereign good, has no phyſical exiſtence. The ſupreme good he defined to be that which is always the ſame. Good he therefore conſidered abſtractedly, as reſiding in the Deity, and he ſeems to have maintained, that all things which exiſt are good by their participation of the firſt good, and that in the nature of things there is no real evil. When Euclid was aſked his opinion concerning the gods, he replied, "I know nothing more of them than this; that they hate inquiſitive perſons." Brucker's Hiſt. Phil. by Enf. v. i.

Euclid, known to every well educated youth by his "Elements," was, according to the teſtimony of Pappus and Proclus, a native of Alexandria, in Egypt, where he flouriſhed and taught the mathematics in the reign of Ptolemy Lagus, about 300 years before Chriſt. His was the firſt mathematical ſchool in that far famed city, where, till its conqueſt by the Saracens, moſt of the eminent mathematicians were either born, or ſtudied. To Euclid, and to thoſe immediately educated by him, the world has been indebted for Eratoſthenes, Archimedes, Apollonius, Ptolemy, &c. "The Elements," to which we have already referred, are not to be wholly attributed to Euclid, many of the invaluable truths and demonſtrations contained therein were diſcovered and invented by Thales, Pythagoras, Eudoxus, and others; but Euclid was the firſt who reduced them to regular order, and who probably interwove many theorems of his own, to render the whole a complete and connected ſyſtem of geometry. "The Elements" conſiſt of fifteen books, but the laſt two are ſuſpected to have been written 200 years after Euclid's death, by Hypſicles of Alexandria. The beſt edition publiſhed in this country is that printed at Oxford, in folio, in 1703; but the moſt common edition in our ſchools is that by the late learned Dr. Simſon. Euclid is ſaid to have been a perſon of agreeable and pleaſing manners, and admitted to habits of friendſhip and familiarity with king Ptolemy, who once demanded of the mathematician if he could not direct him to ſome ſhorter and eaſier way of acquiring a knowledge of geometrical truths, than that which he had exhibited in his "Elements," to which Euclid replied, that "there was no royal road to geometry."

Euclid, as a writer on muſic, has ever been held in the higheſt eſtimation by all men of ſcience who have treated of harmonics, or the philoſophy of ſound. As Pythagoras was allowed by the Greeks to have been the firſt who found out muſical ratios, by the diviſion of a monochord, or ſingle ſtring, a diſcovery which tradition only had preſerved, Euclid was the firſt who wrote upon the ſubject, and reduced theſe diviſions to mathematical demonſtration.

His "Elements" were firſt publiſhed at Baſil, in Swiſſerland, 1533, by Simon Grynæus, from two MSS. the one found at Venice, and the other at Paris. His "Introduction to Harmonics," (Εισαγωγη ἁρμονικη,) which in ſome MSS. was attributed to Cleonidas, is in the Vatican copy given to Pappus; Meibomius, however, accounts for this, by ſuppoſing thoſe copies to have been only two different MS. editions of Euclid's work, which had been reviſed, corrected, and reſtored from the corruptions incident to frequent tranſcription by Cleonidas and Pappus, whoſe names were, on that account, prefixed. It firſt appeared in print with a Latin verſion, in 1498, at Venice, under the title of "Cleonidæ Harmonicum Introductorium:" who Cleonidas was, neither the editor, George Valla, nor any one elſe pretends to know. It was John Pena, a mathematician in the ſervice of the king of France, who firſt publiſhed this work at Paris, under the name of Euclid, in 1557. After this, it went through ſeveral editions with his other works.

His "Section of the Canon," (Κατατομη κανονος,) follows his "Introduction;" it went through the ſame hands and the ſame editions, and is mentioned by Porphyry, in his Commentary on Ptolemy, as the work of Euclid. This tract chiefly contains ſhort and clear definitions of the ſeveral parts of Greek muſic, in which it is eaſy to ſee that mere *melody* was concerned; as he begins by telling us, that the ſcience of *harmonics* conſiders the nature and uſe of melody, and conſiſts of ſeven parts: ſounds, intervals, genera, ſyſtems, keys, mutations, and melopœia; all which have been ſeverally conſidered in the diſſertation.

Of all the writings upon ancient muſic, that are come down to us, this ſeems to be the moſt correct and compreſſed: the reſt are generally looſe and diffuſed; the authors either twiſting and diſtorting every thing to a favourite ſyſtem, or filling their books with metaphyſical jargon, with Pythagoric dreams, and Platonic fancies, wholly foreign to muſic. But Euclid, in this little treatiſe, is like himſelf, cloſe and clear; yet ſo mathematically ſhort and dry, that he beſtows not a ſyllable more upon the ſubject than is abſolutely neceſſary.

His object ſeems to have been the compreſſing into a ſcientific and elementary abridgment, the more diffuſed and ſpeculative treatiſes of Ariſtoxenus. He was the D'Alembert of that author, explaining his principles, and, at the ſame time, ſeeing and demonſtrating his errors. The muſical writings of Rameau were diffuſed, obſcure, and indigeſted; but M. D'Alembert, extracting the eſſence of his confuſed ideas, methodized his ſyſtem of a *fundamental baſe*, and compreſſed, into the compaſs of a pamphlet, the ſubſtance of many volumes. See Elemens de Muſique, ſuivans les Principes de Rameau.

According to Dr. Wallis, (Phil. Tranſ. No. 242, and Lowthorp's Abridg. v. i.) Euclid was the firſt who demonſtrated that an octave is ſomewhat leſs than *ſix whole* tones; and this he does in the 14th theorem of his "Section of the Canon." In the 15th theorem he demonſtrates that a fourth is leſs than two tones and a half, and a fifth leſs than three and a half; but though this proves the neceſſity of a temperament upon fixed inſtruments, where one ſound anſwers ſeveral purpoſes, yet he gives no rules for one, which ſeems to furniſh a proof that ſuch inſtruments were at leaſt not *generally* known or uſed by the ancients.

What Ariſtoxenus called a *half-tone*, Euclid demonſtrated to be a ſmaller interval, in the proportion of 256 to 243. This he denominated a *limma*, or *remnant;* becauſe giving to the *fourth*, the extremes of which were called *ſoni ſtabiles*, and were regarded as fixed and unalterable, the exact proportion of 4 to 3, and, taking from it two major tones $\frac{8}{9}\times\frac{8}{9}$, the limma was all that remained to complete the diateſſaron. This diviſion of the diatonic genus being thus, for the firſt time, eſtabliſhed upon mathematical demonſtration, continued in favour, ſays Dr. Wallis, for many ages. But this is further explained in other articles.

EUCOMIS, in *Botany*, from ευκομης, *having beautiful hair*, alluding to the leafy tuft of barren bracteas, which crowns the ſpike of flowers. See Coma.—L'Herit. Sert. Angl. 17. Ait. Hort. Kew. v. 1. 432. Schreb. 798. Willd. Sp. Pl. v. 2. 92. Mart. Mill. Dict. v. 2. (Baſilæa; Lamarck

Encycl. v. 1. 382. t. 239. Juſſ. 52. Venten. v. 2. 163. Fritillaria; Linn. Gen. 164.) Claſs and order, *Hexandria Monogynia*. Nat. Ord. *Coronariæ*, Linn. *Aſphodeli*, Juſſ.

Gen. Ch. *Cal.* none. *Cor.* of one petal, inferior, bell-ſhaped, regular, permanent, in ſix deep, equal, oblong, obtuſe, ſpreading ſegments. *Stam.* Filaments ſix, ſhorter than the corolla, awl-ſhaped, dilated at the baſe and united by that part into a concave nectary, attached to the bottom of the corolla; anthers oval. *Piſt.* Germen ſuperior, ovate, with three furrows; ſtyle awl-ſhaped; ſtigma ſimple. *Peric.* Capſule ovate, three-lobed, of three cells. *Seeds* numerous, ſmall, ovate.

Eſſ. Ch. Calyx none. Corolla inferior, in ſix deep, ſpreading, permanent, equal ſegments. Filaments united at their baſe into a concave nectary, attached to the corolla.

1. E. *nana*. Ait. Hort. Kew. v. 1. 432. Jacq. Hort. Schoenbr. v. 1. 47. t. 92. (Fritillaria nana; Linn. Mant. 223.) Stalk club-ſhaped. Leaves numerous, broad-lanceolate, crenate. Barren bracteas elliptical.—Native of the Cape of Good Hope, as are all the known ſpecies. *Bulb* ovate, rather large. *Leaves* radical, about eight, pale-green, ſpreading, recurved, obovato-lanceolate, ſomewhat acute. *Stalk* ſolitary, a ſpan high, green, ſwelling conſiderably upwards, bearing a ſhort ſpike of green drooping *flowers*, ſurmounted with a tuft, about as long as the ſpike, conſiſting of elongated, elliptical, barren *bracteas*. It is kept in the greenhouſe, and flowers in the ſpring, but is ſcarcely cultivated except for the ſake of curioſity.

2. E. *bifolia*. Jacq. Ic. Rar. v. 2. t. 449. Coll. v. 4. 215. Curt. Mag. t. 840. (Melanthium maſſoniæfolium; Andr. Repoſ. t. 368.)—Stalk club-ſhaped. Leaves two, elliptical, depreſſed. Bracteas all longer than the flowers, pointed, recurved.—The *leaves* are ribbed, entire, very broad. *Stalk* very ſhort, green. Barren and fertile *bracteas* uniform, and all longer than the *flowers*, which are ſeſſile and erect.

3. E. *purpurea*. (E. purpureocaulis; Andr. Repoſ. t. 369.) Stalk club-ſhaped. Leaves numerous, obovate, obtuſe, depreſſed. Fertile bracteas ſhorter than the flowers; barren ones linear-lanceolate.—Drawn by Mr. Andrews in the garden of G. Hibbert, eſquire.—The broad, depreſſed, numerous *leaves*; thick, violet *ſtalk*; and numerous, narrow, purple-edged leaves of the crown, readily diſtinguiſh this ſpecies.

4. E. *regia*. Ait. H. Kew. v. 1. 433. (Fritillaria regia; Linn. Sp. Pl. 435. Corona regalis, lilii folio crenato; Dill. Elth. t. 92, 93.)—Stalk cylindrical. Leaves tongue-ſhaped, crenate, depreſſed. Barren bracteas elliptical.—This moſt reſembles the firſt ſpecies in ſize, habit, colour, and the crenate edges of its *leaves*; but differs in its longer cylindrical *ſtalk*. It has been much longer cultivated than any other of the genus.

5. E. *undulata*. Ait. ibid. Curt. Mag. t. 1083. (E. regia; Redout. Liliac. v. 3. t. 175. Baſilæa; Lamarck f. 1.)—Stalk cylindrical. Leaves ovate-oblong, undulated, ſpreading. Barren bracteas almoſt as long as the ſpike.—Introduced in 1760 by Mr. Miller, who, from its bloſſoming in autumn, which is not invariable, named it *Fritillaria autumnalis*. *Stalk* taller than in the laſt. *Leaves* narrower and longer. Mr. Gawler obſerves that their undulations diſappear as they decay.

6. E. *punctata*. L'Herit. Sert. Angl. t. 18. Curt. Mag. t. 913. (Baſilæa; Lamarck f. 2.)—Stalk cylindrical. Leaves lanceolate, channelled, ſpreading. Spikes many times longer than the barren bracteas.—The long narrow *leaves*, *ſtalk* elegantly ſpeckled with violet, and eſpecially the great extent of the *ſpike*, which is about a foot in length, render this ſpecies very diſtinct. The *corolla* is of a very pale green. *Germen* violet. The baſes of the *leaves* are externally ſpotted like the ſtalk. It flowers in June or July, and is eaſy of cultivation.

EUCRASY, of ευ, *well*, and κρασις, *temperature*, an agreeable, well-proportioned mixture of qualities, whereby a body is ſaid to be in good order, and diſpoſed for a good ſtate of health.

EUCRYPHIA, in *Botany*, from ευ, *well*, and κρυφιος, *covered*, becauſe the flower-buds are concealed by a peculiar covering. Cavan. Ic. v. 4. 48. Claſs and order, *Polyandria Polygynia*. Nat. Ord. *Tiliaceæ*, Juſſ.

Gen. Ch. *Cal.* Perianth inferior, of five minute, ovate, equal, permanent leaves. *Cor.* Petals five, large, obovate, equal, ſpreading; covered before expanſion with a deciduous veil, ſeparating from the baſe into four ſegments. *Stam.* Filaments inſerted into the receptacle, numerous, awl-ſhaped, ſhorter than the petals; anthers roundiſh, of two cells. *Piſt.* Germen ſuperior, ovate, ſtriated; ſtyles about 12, ſhorter than the ſtamens; ſtigmas ſimple. *Peric.* Capſule ovate, with a woody furrowed bark, burſting at the top and bottom into as many cells as there are ſtyles, each remaining attached by two fibres to the receptacle. *Seeds* ſeveral, obovate, imbricated, each terminated by a ſmall membranous wing.

Eſſ. Ch. Calyx of five ſmall leaves. Petals five, covered before expanſion with a deciduous veil. Capſule of many cells, ſeparating at top and bottom. Seeds winged, imbricated.

1. E. *cordifolia*. Cavan. Ic. v. 4. 49. t. 372.—A fine tree gathered in Chili, by Louis Née, from whoſe herbarium Cavanilles deſcribed it. *Wood* red. *Branches* downy when young. *Leaves* oppoſite, on ſhort ſtalks, ovate, obtuſe, undulated and bluntly crenate, veiny, coriaceous; heart-ſhaped at the baſe; ſmooth above; downy and white beneath; ſcarcely two inches long. *Stipulas* none. *Flowers* axillary, ſolitary, each on a ſtalk about an inch long, with a few ſcales at its baſe. *Petals* white, turning red in drying. *Veil* of the flower externally downy.—It is commonly called in the country *Roble di Chile*, or Chili Oak.

EUDEMIA, in *Ancient Geography*, a ſmall iſland of the Ægean ſea, placed by Pliny in the Thermaic gulf.

EUDÆMON, John Andrew, in *Biography*, a learned Jeſuit, was a native of Candia, and went to Rome in purſuit of knowledge, where he entered himſelf a member of the ſociety of Jeſus. He was afterwards profeſſor of philoſophy, and then of theology in the univerſity of Padua. He was honoured with the eſteem and friendſhip of Pope Urban VIII. who appointed him the chaplain to his own nephew cardinal Barberini, when he was ſent papal legate into France. He died at Rome in 1625, leaving behind him in various publications many teſtimonials to his talents and learning. He was ſuſpected to be the author of a work entitled "Admonitio ad Regem Ludovicum XIII." which attacked the authority of the kings of France, in matters of an eccleſiaſtical nature. This treatiſe brought the ſociety, of which Eudæmon was a member, into great and general diſrepute; it was likewiſe cenſured by the faculty of the Sorbonne, and the aſſembly of the clergy at Paris, and condemned by the parliament. Moreri.

EUDEMUS, in *Biography*, a name, it would appear, common to ſeveral phyſicians in different ages, of whom little is known with any degree of certainty or preciſion. One Eudemus is mentioned by Galen as contemporary with Herophilus, in the 37th age, and is compared with the latter in reſpect to his anatomical ſkill, eſpecially relative to the nerves. Another Eudemus is ſaid to have ſuffered death for his crimes, in the year 31 of the Chriſtian era. And others of the ſame name, as Eudemus the vender of antidotes, Eudemus of Chio, are occaſionally mentioned. See Eloy. Dict. Hiſt.—Le Clerc Hiſt. de la Medecine.

Eudemus of Rhodes was a pupil of Ariſtotle. The Ethics of Ariſtotle are inſcribed to him, and ſome ſuppoſe them to have been written by him.

EUDES, duke of Aquitain, ſucceeded to his dukedom towards the cloſe of the ſeventh century. When Pepin Heriſtal laid claim to the royal authority in France, Eudes declared himſelf independent, and ſeized upon the remainder of Aquitain, and in a ſhort time by force of arms made himſelf maſter of all the country lying between the Loire, the Ocean, the Pyrenées, Septimania, and the Rhone. In 721 he defeated Zama, lieutenant of the Saracen caliph, who had invaded Gaul, under the walls of Toulouſe, but in a few years afterwards he found it neceſſary to make an alliance with Munuza, another Saracen general, to whom he gave his daughter in marriage. After this his country was completely over-run by the Saracens, over whom, by the aid of Charles Martel, he obtained, in 732, a complete victory, which delivered France from the Mahometan yoke. Eudes died in 735, leaving behind him three ſons by his wife Valtrude, who was the near relation of Pepin. Moreri. Univer. Hiſt.

EUDES, JOHN, born at Rye in Lower Normandy, in the year 1601, was brother of the celebrated hiſtorian Mezerai, and received his education at Caen, under the care of the Jeſuits, where he was afterwards entruſted with the ſuperiority of the houſe belonging to the congregation. In 1643 he quitted the duties of this inſtitution, and undertook the eſtabliſhment of another, of which he became the firſt ſuperior as well as founder. This was denominated "The congregation of Jeſus and Mary," and the principal object of it was to provide a ſeminary for the inſtruction of young perſons in piety and ſacred knowledge, and to form a body of religioniſts, influenced by greater fervour and exaltation in their devotional feelings, than was encouraged by the regulations of the ſociety of which he had been a member. He died in 1680, at the age of ſeventy-nine. He is deſcribed as having been an excellent and well meaning man, but myſtical and highly enthuſiaſtic. As a preacher and inſtructor of youth, he was very popular; but his writings evince little knowledge and leſs judgment, though they exhibit a devotional ſpirit, tinctured with large portions of ſuperſtitious credulity. The moſt remarkable of his pieces are (1) A treatiſe "On the Devotion and Office of the Heart of a Virgin; (2) "Man's contract with God;" and, (3) ſome particulars concerning a peaſant in Normandy, whom he regarded as under divine inſpiration, entitled "The life of Mary of the Vallies." Moreri.

EUDIOMETRY. This term is applied to thoſe proceſſes which have been employed to aſcertain the purity, or, in other words, the degree of oxygenation of any gaſeous mixture, and eſpecially of atmoſpherical air.

A conſiderable variety of methods have been uſed by chemiſts, all of which, though eſſentially different, agree in acting upon the oxygenous portion alone, the azot being in all caſes left as the unchanged reſidue. The following are the ſeveral methods employed.

Of nitrous gas as an eudiometer.—This was the firſt eudiometer uſed by Dr. Prieſtley in his original experiments on air, which immediately followed the diſcovery of oxygen by this illuſtrious philoſopher. If nitrous gas be mixed with *oxygen gas*, in a glaſs jar over water, in the proportions in which they ſaturate each other, to form nitric acid, the gaſes will totally diſappear, a ruddy fume is ſeen at the moment of mixture, and the water will riſe to the top of the jar, leaving unabſorbed only the unavoidable impurities of the gaſes. If, on the other hand, nitrous gas be mixed with *atmoſpherical air*, or any other admixture of oxygen and azot, the former alone of the two will be condenſed by and with the nitrous gas, and the azot will remain unaltered. Hence by meaſuring the reſpective quantities of the gaſes employed, and the quantity abſorbed, the purity of the atmoſpherical air may be aſcertained, (ſuppoſing it known by previous experiment what are the exact proportions in which nitrous gas and oxygen ſaturate each other, and become totally abſorbable by water.) Thus, for example, if 100 meaſures of nitrous gas be added to the ſame quantity of common air; and the two compleatly mixed, the bulk after ſuch mixture will not be 200 meaſures, but only about 108, and conſequently 92 meaſures will have been abſorbed; which laſt, therefore, conſiſt of all the oxygen of the air, with ſo much of the nitrous gas as has been employed to ſaturate it. This reſult Dr. Prieſtley was in habit of denoting, for brevity ſake, by the expreſſion that the air was of the purity of 108, by which he always meant that when 100 of nitrous gas, and 100 of the air to be examined were mixed, the reſidue after the mutual action of the airs was over, was of the number ſpecified. The quantity of the two airs abſorbed being known, the portion which is eſtimated to belong to the oxygen muſt therefore depend on the proportion in which nitrous and oxygen gaſes ſaturate each other, which requires another elementary experiment. Thus in the inſtance before us, if three parts of nitrous gas ſaturate one part of oxygen, the 92 parts which have diſappeared are compoſed of 69 of the former gas, and 23 of the latter, and hence the compoſition of the 100 parts of atmoſpherical air examined, will be 23 of oxygen, and the remainder unabſorbed reſidue chiefly azotic.

A number of valuable experiments by Fontana, Ingenhouz, and eſpecially by Mr. Cavendiſh, made on this ſubject, have ſhewn that different portions of the very ſame mixture of nitrous gas and oxygen will experience a prodigious difference of abſorption according to the width of the tube in which they are mixed, the order of mixture, the time of ſtanding together, the degree of agitation uſed, and other manipulations. Thus Mr. Cavendiſh obſerved, that if one meaſure of nitrous gas and as much common air be rapidly mixed, and immediately ſhaken, the abſorption will be nearly half the entire contents, but if the airs are ſuffered to remain in contact for about a fourth of a minute before they are ſhaken, the abſorption will be no more than about .8. The nature of the water alſo in which the experiment is made is found very materially to influence the reſult. By attending to every circumſtance of the kind, Mr. Cavendiſh, with that admirable accuracy which diſtinguiſhes all the reſearches of this eminent philoſopher, was enabled to obtain very ſatisfactory reſults as to the uniform nature of atmoſpherical air.

Still, however, the difficulties of employing this mode of analyſis with ſufficient preciſion in all admixtures of oxygen and azot have been found ſo great, and the apparent anomalies ſo numerous, that it has been long nearly abandoned by chemiſts, till of late the ſubject has been revived by Mr. Dalton, who has added ſome important obſervations, which require ſome notice in this place. (See the Mancheſter Tranſactions. New ſeries.)

Mr. Dalton gives the following experiments:

If 100 meaſures of common air be thrown up to 36 meaſures of nitrous gas in a tube only 3-10ths of an inch wide, and 5 inches long, and no agitation be uſed, in a few minutes the whole will be reduced to 79 or 80 meaſures, and exhibit no ſigns of either oxygen or nitrous gas, but will conſiſt entirely of azot.

If on the other hand 100 meaſures of common air be thrown up to 72 of nitrous gas, in a wide veſſel over water, ſuch as to form a thin ſtratum of air, and an immediate agitation be uſed, both the oxygen and the nitrous gas will, as before, totally diſappear, and the reſidue, as before, will alſo be 79 or 80 meaſures of azot.

If in the laſt experiment leſs than 72 meaſures of nitrous gas be uſed, there will be a reſiduum containing ſome oygen; if more, the reſidue will contain nitrous gas.

From theſe elementary experiments Mr. Dalton infers that the oxygen, contained in 100 parts of common air, may unite totally either with 36 parts of nitrous gas, or with 72, double that quantity, but with no intermediate portion. To inſure the former effect, the gaſes muſt be mixed in a narrow veſſel without agitation; to inſure the latter the veſſel muſt be large, and the points of contact between the ingredients muſt be increaſed by agitation. But in the ordinary circumſtances of the experiment, Mr. D. ſuppoſes that both theſe effects partially take place, ſo that one part of the oxygen unites with the nitrous gas in the ſmaller proportion, and another in the larger; and hence he accounts in a very ingenious and ſatisfactory manner for the greater part of the apparent anomalies which have been obſerved in the employment of nitrous gas in eudiometry. Therefore, he obſerves, to uſe nitrous gas for the purpoſe of eudiometry, we muſt attempt to form one or other of theſe combinations wholly, and he prefers that with the ſmalleſt proportion of nitrous gas, in the following way:

Take a narrow tube of the dimenſions above given, add 100 parts of common air to about 36 of nitrous gas, and when the diminution is complete, without agitation, transfer the reſidue to another tube and meaſure it; then 7-19ths of the loſs will be due to the oxygen preſent.

But a ſtronger objection ariſes againſt the employment of nitrous gas in its aeriform ſtate, owing to the difficulty of obtaining this gas of uniform purity. From a very elaborate ſeries of experiments on this ſubject, undertaken by Humboldt and Vauquelin, (Ann. Chem. tom. 28.) it appears that when nitric acid of any ſtrength is poured upon copper wire (which is the uſual mode of obtaining nitrous gas,) an efferveſcence more or leſs vehement takes place, and a gas is diſengaged, conſiſting of nitrous gas, but always mixed with more or leſs of azotic gas, and ſometimes nitrous oxyd, and it is this varying portion of azot which conſtitutes the chief difficulty and trouble in the employment of nitrous gas in eudiometry. The quantity of azot is found to depend largely on the ſtrength of the acid being from about one-tenth or leſs to nearly half the entire gas. According to Humboldt, the degree of ſtrength of acid which produces the pureſt nitrous gas, is that in which the ſpecific gravity is about 1.15 to 1.17, or from 17 to 21 of Beaume's areometer. Mr. Dalton finds that nitric acid diluted with an equal bulk of water poured on copper and mercury, without any artificial heat being uſed, gives a nitrous gas nearly pure, or with only from two to three per cent. of azot.

The proportion of azotic impurity in any mixture of this with nitrous gas, is moſt conveniently aſcertained by agitating the gas with a ſolution of green ſulphat of iron, which abſorbs the nitrous gas without materially affecting the other. This experiment was firſt made by Dr. Prieſtley, who found that the ſolution of iron acquired thereby a reddiſh or olive brown colour, and a very acid ſtyptic taſte. Other chemiſts have alſo found a certain quantity of ammonia in the ſolution.

To obviate the objections brought againſt the uſe of nitrous gas, in the gaſeous form, as an eudiometer, Mr. Davy has ingeniouſly applied to this purpoſe the ſolution of ſulphat or muriat of iron, ſaturated with nitrous gas as above-mentioned; and this, with a few precautions, is found to anſwer with great preciſion, and to be applicable with little trouble to all caſes of the analyſis of gaſes where oxygen is one of the ſubſtances ſought for. The mode of uſe in ordinary caſes is as ſimple as poſſible. The gas is put into a graduated eudiometer tube, ſome of the ſolution is poured in, and by very gentle agitation for about a minute, the whole of the oxygen is abſorbed. The chief precautions required are, not to uſe the ſame ſolution twice, to keep it in a well-ſtopped bottle, and particularly to remove it from the gas under analyſis as ſoon as the utmoſt degree of abſorption is produced, as after this time a ſmall increaſe of bulk is again obſervable in the reſidue, owing probably to ſome evolution of gas from the ſolution. It is alſo found that if the ſolution be very highly impregnated with the nitrous gas, and much haſty agitation be uſed, a little of the nitrous gas eſcapes in the gaſeous form into the eudiometer tube, which may be removed by the application of a little ſulphat or muriat of iron. One cubic inch of the impregnated ſolution of moderate ſtrength will abſorb about five or ſix cubic inches of oxygen gas.

Of the ſulphurets as eudiometers.—The eudiometer firſt employed by the illuſtrious Scheele, in his original experiments on the conſtitution of the atmoſphere, ſo early as the year 1779, was a mixture of iron filings and flowers of ſulphur, moiſtened with a little water. By confining a cup of this mixture under a jar of common air over water, this excellent chemiſt obſerved an abſorption ſoon to begin, the water gradually riſing in the jar for about eight hours, after which no further diminution took place, and the reſiduary gas conſiſts chiefly of azot.

This valuable elementary experiment has been employed in eudiometry with great advantage, but modified conſiderably, and a few precautions muſt be taken to avoid inaccuracies. In the firſt place it is to be obſerved that this mixture of iron filings and ſulphur is ſlow in its operation, and moreover, a quantity of hydrogen gas is given out towards the end, which mixes with the reſiduary azotic gas. To leſſen the duration of the experiment the liquid alkaline or earthy ſulphurets have been ſubſtituted to the mixture of iron filings and ſulphur, with great advantage. When atmoſpherical air, confined in a tube, is ſhaken for a few minutes with a little of the liquid ſulphuret of lime, potaſh, or ſoda, the whole of the oxygen is abſorbed in a few minutes.

Guyton has propoſed to haſten the abſorption by heating the ſolution, but it has been found that in this caſe there is ſome danger of expelling from it a portion of ſulphurated hydrogen gas, which would impair the accuracy of the experiment.

A more important ſource of error has been mentioned by Marti, (Journal de Phyſique, tom. 52.) which muſt be avoided. It appears from his experiments that liquid ſulphuret of lime, (and probably the other liquid ſulphurets,) when recently made, is capable of abſorbing a portion of azot as well as oxygen, which, though ſmall, is ſufficient to affect materially the reſult of a delicate experiment. Marti found that when one meaſure of common air was ſhaken with 20 meaſures of the liquid ſulphuret of lime, the entire abſorption amounted to as much as 26 per cent. of the air. But of theſe it is known that only about 21 can be oxygen, and conſequently about 5 of azot muſt have been abſorbed. The experiment being repeated with the ſame ſolution, only 21 per cent. were now abſorbed, ſo that the ſolution had been ſaturated with azot by the previous experiment. The ſame ſolution was then ſhaken with pure azot, but no abſorption took place, which confirmed the fact of the previous ſaturation of the ſulphuret with azot. On the other hand, when a perfectly freſh ſolution was uſed, which immediately after being prepared, had been allowed to cool in a well-cloſed bottle, and only a twentieth of its bulk of common air was confined with it, the latter in a few minutes had diminiſhed full one-half.

It is eaſy to avoid errors from this circumſtance. All that is neceſſary is, previouſly to uſing the liquid ſulphuret as an eudiometer, to ſhake it for a few minutes in a bottle of common air, and it is never neceſſary to uſe more than about two meaſures of the ſulphuret to one of common air. With theſe precautions, the ſulphuret proves a very uſeful and accurate eudiometer.

Of hydrogen gas as an eudiometer.—This ingenious method was propoſed and employed with great ſucceſs by the celebrated Volta. It conſiſts in mixing known proportions of pure hydrogen gas with the air to be examined in a very ſtrong glaſs tube, through which a metallic communication is made, and detonating the contents by the electric ſpark. After the ſhock, a ſudden diminution takes place, owing to the production of water by the detonation of the hydrogen with the oxygen contained in the air examined. The exact ſaturating proportion between the two gaſes has been variouſly given, but an exceſs of hydrogen ſhould be uſed. One hundred parts of oxygen require at the higheſt eſtimation ſomewhat leſs than 200 of hydrogen for ſaturation; ſo that when equal bulks of hydrogen and *atmoſpheric air* are uſed, there is an abundant allowance of hydrogen. Mr. Dalton finds 60 of the latter ſufficient for 100 of common air, and the diminution is very uniformly 60 parts with the above proportions; and hence, if common air contains 21 per cent. of oxygen, the ſaturating proportions of oxygen and hydrogen are 21 of the former to 39 of the latter.

The chief objection to the univerſal uſe of Volta's eudiometer is, that it requires an apparatus to give the electric ſpark, which cannot be always procured; and in all experiments of this kind it is particularly deſirable to employ one uniform mode of experimenting where general reſults are to be eſtabliſhed.

Of phoſphorus as an eudiometer.—Phoſphorus has two diſtinct modes of combuſtion in common air, according to the temperature to which it is raiſed. One of theſe is rapid, and attended with the evolution of a prodigious quantity of light and heat, and it occurs when phoſphorus is heated a little above its melting point, or in common language is ſet fire to. The other takes place in a temperature not exceeding from 90° to 100° at the utmoſt, and is that in which the phoſphorus emits copious fumes, white in the day-time but highly luminous in the dark, and without any ſenſible emiſſion of heat. In either caſe the phoſphorus is *conſumed*, or oxygenated; but it is the ſlow combuſtion without ſenſible heat that is alone employed in eudiometry. The whole apparatus required for the purpoſe is ſimple and convenient of application. Nothing more is neceſſary than to fix a ſtick of phoſphorus in a portion of glaſs tube run through a cork, which looſely fits the open end of the ſmall jar which is to contain the air to be analyzed, and confine it by water. If the temperature is very cold, the proceſs may be aſſiſted by the warmth of the hand. The phoſphorus is immediately ſurrounded by the white luminous fume, which ſlowly falls down to the ſurface of the water, during which time the oxygen of the air is gradually abſtracted by the vaporized phoſphorus, and in conſequence the bulk of the contained air is diminiſhed. The abſorption of oxygen is complete when the contained gas is no longer luminous, which, in a ſmall jar with a ſtick of phoſphorus that traverſes nearly its whole length, requires about half an hour at the heat of from 70° to 80°. The proceſs ſucceeds equally well at a lower temperature, though a longer time is required. The heat cannot be ſafely raiſed more than about 85° or 90°, without danger of kindling the phoſphorus, which may be avoided by obſerving that it melts and becomes gloſſy juſt before it catches fire.

The exact operation of the ſlow combuſtion of phoſphorus uſed in this experiment has been very happily explained by Goettling and Berthollet. When phoſphorus is expoſed to air at any temperature below that of rapid combuſtion, the firſt effect ſeems to be a ſolution of the ſurface in the azot of the ſurrounding air, and this phoſphorized azot inſtantly unites with the oxygen, becomes thereby luminous, and phoſphorus acid abſorbable by water is generated. Hence it is (ſtrictly ſpeaking) only that portion of phoſphorus which becomes diſſolved in the azot which is the eudiometrical ſubſtance; and in confirmation of this it may be added that phoſphorus incloſed in pure oxygen gas is not in any degree luminous, but remains perfectly inactive till the heat is raiſed to the point of ſtrong combuſtion. On the other hand, if the pureſt poſſible azot is paſſed into a jar full of water, and containing a ſtick of phoſphorus, the gas only becomes luminous for a very ſhort time, after which this appearance ceaſes, but the azot continues to ſaturate itſelf with phoſphorus. If now a bubble of common air or oxygen is let up into this phoſphorized azot, the luminous appearance immediately returns, and continues ſo till all the oxygen is exhauſted. Phoſphorus, therefore, furniſhes alſo an uſeful teſt of the purity of azot, by not becoming luminous in it, but by enabling it to become luminous as ſoon as a particle of oxygen is added.

One circumſtance of importance ſhould be added, which is, that azotic gas in ſaturating itſelf with phoſphorus is found to expand about 1-40th of its bulk, which accounts for the apparent difference in the compoſition of common air as determined by phoſphorus or by other eudiometrical ſubſtances. After all abſorption has ceaſed, when phoſphorus is uſed, the apparent loſs is not more than from 20 to 21 per cent. of the atmoſpherical air employed, whereas with all the other eudiometrical proceſſes the loſs is from 21 to 22 per cent., but this difference may be chiefly accounted for by the expanſion of the reſidual azot from its ſaturation with phoſphorus. It is therefore more accurate to diminiſh the bulk of the reſiduum by 1-40th, and this diminution muſt be thrown into the ſide of the oxygen abſorbed. In analyzing an air much more oxygenous than the atmoſphere, in proportion as the azotic ingredient diminiſhes, the operation of the phoſphorus in removing the oxygen becomes leſs rapid and powerful, and hence either a dilution with pure azot is adviſeable, or ſome other eudiometrical teſt ſhould be preferred.

The general reſults of all the operations of atmoſpherical air have eſtabliſhed it as an inconteſtible truth, that ſcarcely any difference exiſts in the proportion of oxygen, whatever be the height, ſeaſon of the year, climate, and temperature at which the experiment is made, and even where the greateſt changes would be expected from vitiation of air by the reſpiration of crowded aſſemblies of people, and the like, the loſs of oxygen is much leſs than would have been generally expected. Hence the utility of eudiometry as a meaſure of the purity of the atmoſphere has much diminiſhed ſince this fact has been eſtabliſhed, but the numerous and acute reſearches to which the ſubject has led, have been of high importance to this difficult part of chemical reſearch.

Several kinds of apparatus are uſed in eudiometrical experiments, ſome of which may be here deſcribed.

Dr. Hope's eudiometer is the following. (*Plate* X. *Chemiſtry, fig.* 1.) It conſiſts of two parts, the lower of which is a ſhort thick bottle, with an upper and a ſide opening, the latter cloſed by a glaſs ſtopper, and the other receiving a graduated tube cloſed at the top, and accurately fitted by grinding. To uſe it, take off the tube, and fill it quite full of the gas to be examined, and alſo fill the bottle with liquid ſulphuret of lime, and, without ſhaking, ſink it in water, and then immerſe the open end of the graduated tube in the ſame water, and ſlide it upon the bottle and thruſt it in. Then take out the bottle and tube, and ſhake them, to bring the ſulphuret thoroughly in contact with the contained gas, and immerſe the bottle from time to time in water, opening the ſide ſtopper to allow the water to ruſh in, and ſupply the vacuum made by the abſorption of oxygen. This will indeed ſomewhat dilute the eudiometrical liquor, but not ſo much as to prevent it from acting. When all abſorption is over, the quantity of reſidual gas is found by inſpection of the ſcale of the graduated jar.

The apparatus for detonating oxygen and hydrogen, which forms Volta's eudiometer, conſiſts of a very thick graduated glaſs tube, open at bottom, and towards the top are two ſealed holes, admitting the wires by which the electric ſpark is taken. A very uſeful improvement in this apparatus has been introduced by Mr. Pepys, to prevent the violence of the ſhock, either from breaking the glaſs (with moderate quantities) or from throwing out any of the mercury when confined by this fluid. In this improved apparatus, the thick graduated jar is fixed to a heavy iron ſtand, which has a ſtrong ſpring near the foot, that draws out in the manner of the ſteel-yard, when the concuſſion is given, and thus takes off the recoil. *Fig.* 2.

An improved and very uſeful apparatus for nice eudiometrical experiments, is given by Mr. Pepys in the Phil. Tranſ. for 1807, to which we ſhall refer our readers for a full deſcription. It conſiſts of a graduated tube, an elaſtic gum-bottle, furniſhed with a perforated glaſs ſtopper, cloſely fitting to the end of the tube, and another very ſmall tube with a ſurrounding jar for the purpoſe of meaſuring quantities leſs than the ſmalleſt ſubdiviſions of the larger graduated tube. The eudiometrical liquor is put into the elaſtic gum-bottle, and by preſſure is injected ſtrongly up into the larger tube, by which means the action is facilitated, and none of the liquor is ſpilled or waſted.

EUDOCIA, in *Biography*, a Roman empreſs, wife of Theodoſius the younger, was daughter of Leontius, an Athenian philoſopher. She was educated in the ſciences and religion of ancient Greece, and ſo great were her mental acquirements and perſonal beauty, that Leontius divided his property between his ſons, conceiving ſhe could ſtand in need of nothing to recommend her to a proper huſband. About the year 421 ſhe was married to Theodoſius, when ſhe renounced the errors of paganiſm, and received the baptiſmal name of Eudocia, having previouſly been called Athenais. She was reconciled to her brothers; and, having invited them to court, conferred upon them offices of rank and power. Upon the throne, as in a more humble ſtation, ſhe cultivated letters, and employed her talents in the ſervice of the religion to which ſhe was a convert. She put into verſe ſeveral of the books of the Old Teſtament, and wrote paraphraſes on ſome of the Jewiſh prophets. She lived for a conſiderable time in harmony with her conſort; and after the marriage of her daughter to the emperor Valentinian III. ſhe was permitted to pay her vows in a ſplendid pilgrimage to Jeruſalem; and at Antioch ſhe pronounced an oration to the ſenate from a throne of gold. After her return, ſuſpicions were excited of her fidelity in the breaſt of her huſband by his ſiſter Pulcheria, who had been the means of bringing them together by marriage. The object of theſe ſuſpicions was Paulinus, a handſome and accompliſhed man, who held high offices at court, and who was put to death on the occaſion. Eudocia was reduced to a private condition, and allowed to ſeek a retreat in the Holy Land, where ſhe had formerly obtained a high degree of credit by the magnificence of her preſents. Here ſhe devoted herſelf to religious and devotional ſtudies, and died in 460 at the age of 67. In her laſt illneſs, ſhe aſſerted in the moſt ſolemn manner her innocence of the crime for which ſhe had been dethroned and ſuffered baniſhment. Moreri. Gibbon's Hiſt.

EUDOCIAS, in *Ancient Geography*, an epiſcopal town of Aſia, in Pamphylia.—Alſo, an epiſcopal town of Aſia, in the ſecond Galatia.

EUDON, a river of Aſia, in Caria.

EUDOXIANS, a party or ſect of heretics in the fourth century, ſo denominated from their leader Eudoxius, a native of Arabiſſus in Armenia Minor, and patriarch of Antioch, to which he was advanced in 356, and Conſtantinople, to which he was promoted in 359, and which he retained till his death, in 370. He was a great defender of the Arian doctrine, though repreſented as ſomewhat fluctuating and unſteady in his principles. He is charged with being a bitter perſecutor of the Catholics. Of his works, no remains are extant, except ſome fragments of a treatiſe "De Incarnatione Dei verbi;" to which Cave (Hiſt. Lit.) has referred.

The Eudoxians adhered to the errors of the Arians and Eunomians, maintaining that the Son was created out of nothing; that he had a will diſtinct and different from that of the Father, &c.

EUDOXIOPOLIS, in *Ancient Geography*, an epiſcopal town of Aſia, in Piſidia.

EUDOXUS, the *Cnidian*, in *Biography*, was celebrated as an aſtronomer, a geometrician, a phyſician, and legiſlator, but was moſt particularly diſtinguiſhed in the firſt of theſe characters. His firſt preceptor was Archytas, by whom he was inſtructed in the principles of geometry and philoſophy: about the age of 23 he came to Athens. His knowledge of medicine is ſaid to have been obtained in this way. A phyſician, named Theomodonus, obſerving the ardent deſire which he manifeſted for ſtudy, notwithſtanding his extreme poverty, preſumed that he poſſeſſed talents which deſerved cultivation, and therefore took him to his houſe, and afforded him every means of accompliſhing his wiſhes, enabling him, as his own patrimony was ſmall, to attend the ſchools of the philoſophers, particularly that of Plato. Eudoxus afterwards went into Egypt, accompanied by a pupil, named Chryſippus, and here he was introduced by Ageſilaus to king Nectanebis II., and by him to the Egyptian prieſts. He is highly celebrated by the ancients for his ſkill in aſtronomy; but none of his writings on this or any other ſubject are extant. Aratus, who has deſcribed the celeſtial phenomena in verſe, is ſaid to have followed Eudoxus; to whom is attributed the honour of bringing the celeſtial ſphere and the regular aſtronomy from Egypt into Greece. Having left Egypt he taught aſtronomy and philoſophy with great applauſe at Cyzicus, on the Propontis; and he afterwards removed to Athens, where he opened a ſchool, and gained ſo high a degree of reputation, that he was conſulted on ſubjects of policy as well as ſciences, by deputies from all parts of Greece. His death is generally referred to the firſt year of the 107th olympiad, 352 years before Chriſt. See Le Clerc. Hiſt. de la Med. Eloy.

Eudoxus is ſaid by Fabricius (Bibl. Græc. lib. iii. c. 5.) to have written upon muſic, and he gathers from Theon of Smyrna, p. 94, that Eudoxus was the firſt who expreſſed the ratios of concords by numbers, and who diſcovered that grave and acute ſounds depend on the ſlow or quick vibrations of the ſounding body.

EUDRACINUM, in *Ancient Geography*, a town placed by the Itinerary of Antonine on the Alps, between Summus Penninus and Auguſta Prætoria.

EUDRAPA, Eder, or *Edir*, a town of Aſia, ſituated in Meſopotamia, W.S.W. from the town of Carmanda.

EUDROME, in the *Ancient Muſic*, the name of an air played by hautbois at the Sthenian games, inſtituted at Argos in honour of Jupiter. Hicorax the Argian was the inventor of this air.

EVE, the firſt woman, and mother of the human race. The hiſtory of her formation and other particulars is recorded in the Hebrew Scriptures (Gen. ii. iii. iv.); and it is needleſs to recite from Bayle and others the abſurd fables invented concerning her by the Jewiſh rabbis.

Eve. See Vigil.

EVEA, or Eva, in *Ancient Geography*, the ancient name of Byblos, a town of Phœnicia.

Evea, in *Botany*, Aublet Guian. v. 1. 100. t. 39. Juſſ. 208. See Callicocca, ſpec. 10.

EVECTION, in *Aſtronomy*, the moſt conſiderable of the lunar irregularities, and the firſt that was known to the ancient aſtronomers. It was diſcovered by Ptolemy. Its general and conſtant effect is to diminiſh the equation of the centre in the ſyzygies, and to increaſe it in the quadratures. If this diminution and augmentation were always the ſame, the evection would depend alone on the angular diſtance of the moon from the ſun; but the abſolute value of the evection depends likewiſe on the diſtance of the moon from the perigee of her orbit. After a number of trials and obſervations, it was found that this inequality could be repreſented very exactly by ſuppoſing it proportional to the ſine of double the angular diſtance of the moon from the ſun, *minus* the mean anomaly of the moon. The co-efficient to this proportion is 1° 20′ 30″.

The period of the evection differs but little from the periodic revolution of the moon: it is 27.178533 days. The evection is cauſed by the action of the ſun upon the moon, and may be explained by ſuppoſing a change to take place in the excentricity of the moon's orbit, and at the ſame time a motion in the apogee.

Ptolemy ſuppoſed the epicycle of the moon to be carried along in an excentric circle, and that it was nearer to us in the quadratures than in the conjunctions and oppoſitions; ſo that to explain this inequality at the ſame time with the equation of the centre, he imagined an excentric and an epicycle. It is curious to trace the progreſs of theſe diſcoveries, and the hiſtory of the firſt obſervations of the evection has been tranſmitted in the words of Ptolemy himſelf. (Almageſt. lib. v. cap. 1.)

In obſerving, ſays he, with care, the order of this inequality, we took notice that there was no other than the firſt and ſimple inequality in the conjunctions and oppoſitions, and even in the quadratures when the moon was in apogee or perigee, (meaning by the ſimple inequality the equation of the centre); but we may be aſſured that this is not ſufficient to calculate the particular motion of the moon in other aſpects. The ſecond inequality, (*i. e.* the evection,) is connected with the diſtance of the moon from the ſun, and is re-eſtabliſhed and diſappears in the conjunctions and oppoſitions, and is greateſt in certain quadratures. We diſcovered this inequality by the obſervations tranſmitted by Hipparchus, and by thoſe which we have made by means of an inſtrument conſtructed for the expreſs purpoſe of meaſuring the difference of longitude on the zodiac between the moon and the ſun.

Ptolemy found that there was a difference of $2\frac{2}{3}^\circ$ between the obſerved and the calculated place (when the firſt inequality or equation of the centre was only uſed) when the moon in quadrature was three ſigns from the apſide. (Almageſt. v. 3.) Then the ſun being in the apogee or perigee of the moon, the inequality, which ſhould have been 5°, was found $7\frac{2}{3}^\circ$; to explain which he ſuppoſed the epicycle as above-mentioned.

Copernicus, to explain the evection, employed two epicycles. The ſmall epicycle is ſuppoſed to deſcribe the circumference of the great one in the ſpace of an anomaliſtic revolution, and contrary to the order of the ſigns; while the moon deſcribes the ſmall epicycle contrary to the order of the ſigns in $14^d\ 18^h$, or in the ſpace of half a ſynodical revolution.

It was in this manner that the ſecond inequality of the moon, called now the evection, was explained till the time of Tycho. It was called by Ptolemy "προσνευσιν, epicycli quaſi annutum," by Copernicus "proſtaphæreſim ſecundi vel minoris epicycli," by Tycho "proſtaphæreſim excentricitatis," and by Bouillaud "evection," which name it ſtill retains.

The evection was explained in a different manner by Horrox about the year 1640; but his theory was not made known till 1673, when Flamſtead calculated his new tables of the moon, upon the principles and numbers given him by Horrox. Theſe tables were publiſhed in the poſthumous works of Horrox in 1673. This hypotheſis is the ſame with that of Arzachel, an aſtronomer who flouriſhed in Spain in 1080, when that country was poſſeſſed by the Arabians, and who applied it to the motion of the ſun. Let T be the centre of the earth (*Plate* XII. *Aſtronomy*, *fig.* 107.), C the mean place of the centre of the orbit which a planet is ſuppoſed to deſcribe; ſo that T C A may be the line of the apſides, and T C the excentricity of the planet. If the centre of the orbit, inſtead of being fixed in C, be ſuppoſed to deſcribe the circumference of a ſmall circle A C B, there will reſult a double effect: 1. The line of apſides T A will change its poſition, and inſtead of remaining conſtantly in the direction T C A, it will paſs, for example, into the poſition T G, and will make with the firſt poſition an angle A T G. 2. The excentricity, inſtead of being equal to the original quantity T C, will become T G, T B, &c. This hypotheſis was invented by Arzachel to explain a ſuppoſed diminution of the excentricity of the ſun's orbit, which he had inferred from ſome defective obſervations, and has not only been adopted by Horrox to deduce this inequality of the moon, but by Flamſtead, Halley, and Newton, for the ſame purpoſe.

Kepler had already announced that he employed an excentricity of the lunar orbit which varied every year; but Horrox was led likewiſe to this hypotheſis by obſervations of the diameter of the moon; for about this time the application of micrometers to teleſcopes enabled aſtronomers to determine the apogee and perigee of the moon much more exactly than formerly. From theſe obſervations he perceived that the apogee of the moon was about 25° more advanced when the diſtance from the ſun to the apogee of the moon was 45° or 225°, than when it was 135° or 315°: hence the motion of the apogee, inſtead of being uniform, ſeemed to have an annual libration of more than 12°. This variation in the motion of the apogee being once known, its connection with a change of excentricity was not difficult to be diſcovered. Both Halley and Newton employed the above hypotheſis. According to the method of Newton the centre A of the orbit of the moon (*fig.* 108.) deſcribes a circle A C B, the earth being at T. Thus T C expreſſes the mean excentricity of the moon; T A the greateſt excentricity, and T B the leaſt; T C being to C B as the mean excentricity is to its difference from the leaſt, or as the total ſine is to the ſine of 12° 18′, which is the greateſt equation of the apogee. It is likewiſe ſuppoſed that if the angle A C G be taken equal to double the annual argument, or the diſtance between the ſun and the mean apogee of the moon for a given time, the angle C T G will be the equation of the apogee, and T G the excentricity for the ſame time. Then in the triangle T C G, the two ſides and included angle being given, we have the ſum of T C, and C G is to their difference as the tangent of half A C G, (or the annual argument, whoſe double is A C G,) is to the tangent of half the difference of the unknown angles. This is reduced to a conſtant logarithm, which added to that of the tangent of the mean annual argument, gives the annal argument corrected; and this, added to the place of the ſun, gives the true place of the apogee of the moon. This is the form which Halley employed in his lunar tables.

It eſcaped the obſervation of Flamſtead, Halley, and Newton, that this equation might be calculated without ſuppoſing a variable excentricity and libration of the apogee. Euler employed this method, of which the following is the demonſtration.

Let L (*fig.* 109.) be the moon, T the earth, C the mean centre of the lunar orbit, G the centre for a given moment; C T the mean excentricity of the moon, C L T the half of the mean equation of the orbit, becauſe it is the double excentricity which produces the whole equation; G L T the half of the evection for the time given, and repreſented in Newton's method by an augmentation of excentricity; C L G is the difference of theſe two equations, or the effect which the change of excentricity, and the libration of the apogee, produce upon the half equation. To find by a ſimple operation this angle C L G, which is the half of the evection, it muſt be remembered that when this angle is the greateſt, or when L C is perpendicular to C G, the angle C L G is 40′, that is, the conſtant relation between C L and C G is ſuch, that the value of L can only be 40′ when it is the greateſt, or 1° 20′ for the whole evection. When the angle L C G is oblique, the angle C L G will diminiſh, and that in the ratio of the perpendicular G D to the line C G, or as the ſine D C G to radius. Hence the evection will be 80′ ſin. D C G; but the angle D C G = A C L − A C G is the mean anomaly of the moon, minus twice the diſtance of the ſun from the moon's apogee, or what is the ſame, twice the diſtance of the moon from the ſun, minus the mean anomaly of the moon, which forms the argument of evection.

The half evection, or angle G L C, is equal 40′ ſin. (2 diſt. ☾ ☉ — m. anom. ☽.) This is the form in which it is uſually found in the lunar tables.

When we come to treat of the theory of the moon, and the lunar inequalities, we ſhall have occaſion to reſume this ſubject, and to ſhew how correctly this equation is derived from the law of univerſal gravitation; we ſhall confine ourſelves at preſent to a very general explanation of the phyſical cauſe of this phenomenon.

When the ſun correſponds to the apogee or perigee of the moon, that is, when the line of apſides of the moon coincides with the line of the ſyzygies, the central force of the earth upon the moon, which is the weakeſt in the ſyzygy apogee, receives the greateſt diminution, and the central force, which is the ſtrongeſt at the ſyzygy perigee, there receives the leaſt diminution, therefore the difference between the central force perigee and the central force apogee will then be the greateſt, and the difference of the diſtances will be augmented, that is, the excentricity will become greater, and obſervation ſhews that the equation is then 7° 40′, whereas it does not exceed 5° when the line of the quadratures coincides with the line of the apſides.

The formula for the evection in the lateſt tables is 1°20′28″ ſin (2 diſt. ☾ ☉ — mean anomaly ☽); from which it is eaſy to follow the ſucceſſive variations of this equation, for it is only requiſite to conſider the different values which its argument can take. If it be required, for inſtance, to determine when it arrives at its maximum, we have only to inveſtigate the caſe in which the angle 2 diſt. ☉ ☽ — m. anom. ☽ becomes equal to 90°, or 270°, or its ſine equal to unity, the evection will then be equal 1° 10′ 21″: the firſt of theſe values will happen in the quadratures, when the mean anomaly is equal 90°, for then 2 diſt. ☾ ☉ = 180° 2 diſt. ☉ ☽ — m. anom. ☽ = 180° − 90° = 90°; on the contrary, the evection will diſappear, when the argument is zero or 180°, this will happen in the ſyzygies when the moon is either perigee or apogee, for then the diſtance of the moon from the ſun is equal 0° or 180°, and the ſame of the mean anomaly. But by the various combinations of the two angles which form the argument of evection, the greateſt and leaſt values will arrive, even in ſeveral other points of the orbit. In general, in the conjunctions, the evection will have a contrary ſign to the equation of the centre, for its argument is reduced to — mean anom. ☽, which gives a negative ſign if the anomaly is leſs than 180°, and a poſitive ſign if it is greater; but in the firſt caſe the equation of the centre is additive, and in the ſecond it is ſubtractive. It is eaſy to comprehend that it will be the ſame in the oppoſitions, hence it follows that in the ſyzygies the evection is ſubtractive from the equation of the centre, on the contrary it is additive in the quadratures. Thus the firſt obſervers that examined the theory of the moon's motion only by means of eclipſes, and with no other view but to predict thoſe phenomena, always found the equation of the centre too ſmall, by the quantity of the evection in the ſyzygies.

It is not difficult to find the period of the evection from the variations of the value of the angle on which it depends; it is ſufficient to calculate the variations of this angle in a given time; and to conclude, by a ſimple proportion, the number of days neceſſary for it to vary 360°.

The ſynodical motion of the moon in one century is 445267° 6′ 55″.46, multiplying this by two, we have 890534° 13′ 50″.92 for the double of the diſtance of the moon from the ſun, after a hundred Julian years. If from this we take the anomaliſtic motion of the moon, in the ſame interval, or 477198° 41′ 30″.6; the difference 413335° 32′ 20″.3 will be the value of the argument of evection, after 100 Julian years; from whence it appears, that this argument increaſes 360° in a number of days expreſſed by 360.36525, or 27.178533 days; this is the period of the evection, after which period it ſucceſſively takes again the ſame values.

From this it appears, that ſubſtituting, inſtead of theſe angles, their values calculated as above, the argument may be put in the form of a quantity proportional to the time;

for example, if we name the number of days elapſed ſince a given epoch as that of the tables t. The angle 2 diſt. ☽ ☉ —m. anom. ☽ will become $\frac{t \,.\, 360}{27.178533}$, and the evection may be repreſented under this form 1° 20′ 28″ $\left(\frac{360 \,.\, t}{27.178533}\right)$ or ſimply 1° 20′ 28″ ſin. m. t. making $m = \frac{360}{27.178533}$.

EVEILLON, James, in *Biography*, was born at Angers in the year 1542; he was diſtinguiſhed at a very early age for his literary acquirements, and obtained conſiderable eccleſiaſtical preferment, in the place of his birth, till at length he was made grand-vicar to the biſhop. Eveillon was looked up to for his ſuperior knowledge of the rights and uſages of the church; and of every ſubject connected with the councils, the fathers, and the canon law. He was not unfrequently employed in matters relating to church diſcipline, the reformation of breviaries, rituals, and monaſtic inſtitutions. His principal works were entitled "De Proceſſionibus Eccleſiaſticis, in quo earum Inſtitutio, Significatio, Ordo, et Ritus explicantur."—"De recta Pſallendi Ratione;" and "A Treatiſe on Monitions and Excommunications," which has borne a high character in the Catholic communion. Eveillon died at the age of 79, in the year 1621. He was a man of extenſive benevolence, having obtained the title of father to the friendleſs, and the poor, to whoſe relief he devoted the whole of a liberal income, excepting what was abſolutely neceſſary for his own ſupport. Moreri.

EUELPIDIUM, a kind of fluid collyrium.

EUELPISTI, a plaſter deſcribed by Scribonius Largus.

EVELYN, John, in *Biography*, the ſon of Richard Evelyn, eſq. was born at Wotton, in Surrey, in 1620. He received the early part of his education at Lewes, from thence he went to Chriſt church, Oxford. During the civil wars he ſpent his time on the continent, particularly in France and Italy. He married in the year 1647 the only daughter of ſir Richard Browne, the king's miniſter at Paris, and returned to England about the year 1651, where he employed himſelf in literary occupations, chiefly in tranſlating from the French and Latin. He was much inclined to a life of learned leiſure; and in his zeal to forward a ſimilar plan for others he formed a ſcheme for the erection of a college, where perſons might live together in philoſophical retirement, and in the purſuit of common ſtudies. In 1657 he publiſhed a favourable account of the king's character, with a view of preparing his countrymen for the reſtoration of monarchy, and on the return of the exiled Charles, he was graciouſly received, and introduced into public life, though without abandoning his literary purſuits. In 1662 he publiſhed a curious and learned work, containing much uſeful and important information, entitled "Sculptura, or the Hiſtory and Art of Chalcography, or Engraving on Copper." This piece was reprinted in 1755, with additions. Mr. Evelyn practiſed the art himſelf, and is introduced by Mr. Walpole into his catalogue of Engliſh engravers. On the inſtitution of the Royal Society, he was nominated among the firſt fellows and members of the council, and he ever after continued a zealous and truly active member of that learned body. At ſome of the early meetings of the ſociety was read his diſcourſe on foreſt trees, which was the baſis of the treatiſe entitled "Sylva, or a Diſcourſe of Foreſt Trees, and the propagation of Timber in his Majeſty's Dominions, to which is annexed Pomona, or an Appendix concerning Fruit Trees, in relation to Cyder, &c." As a ſequel to this work, he afterwards publiſhed his "Terra, a Philoſophical Diſcourſe of Earth, relating to the Culture and Improvement of it for Vegetation, and the Propagation of Plants." Both theſe works have been reprinted ſeveral times. The edition of the Sylva by Dr. Andrew Hunter, of York, is with plates of all the trees, in which their parts of fructification are accurately diſplayed according to the Linnæan ſyſtem. Mr. Evelyn was appointed, at the deſire of the king, in 1664, one of the commiſſioners of the ſick and wounded ſeamen, and likewiſe a commiſſioner for rebuilding St. Paul's cathedral. How well fitted he was for the latter office was ſhewn by a work which he publiſhed, entitled "A Parallel of the Ancient Architecture with the Modern," tranſlated from the French of Roland Freart, ſieur de Chambray; with additions from Alberti and others. He reſided at this period at his houſe of Sayes-court, near Deptford, which he had in right of his wife; here he cultivated a garden, and was regarded as a great improver of the art of horticulture, and celebrated for the pains which he took in the introduction of exotics into this country. During the reign of Charles, a board of trade was formed, and Mr. Evelyn was appointed one of its members. On this occaſion he drew up a ſmall treatiſe on the origin and progreſs of navigation and commerce, with an aſſertion of the king's title to the dominion of the ſea. Among the papers which he communicated to the Royal Society is a curious letter, given at length in the Biographia Britannica, deſcribing the miſchiefs done to his garden by the ſevere winter of 1683—4. This letter will be read with intereſt, as affording information of the perennials at that time chiefly cultivated in England, and as ſtating the dire effects of rigorous froſt. We ſhall give the concluding paragraph:

"The vines have eſcaped, and of the eſculent plants and ſallads, moſt, except artichokes, which are univerſally loſt; and what I prefer before any ſallad whatever, eaten raw when young, my ſampier is all rotted to the very root. The arboreſcent and other ſedums, aloes, &c. though houſed, periſhed with me, but the yucca and opuntia eſcaped. Tulips, many are loſt, and ſo the Conſtantinople-narciſſus, and ſuch tuberoſæ as were not kept in the chimney corner, where was a continual fire. Some anemonies appear, but I believe many are rotted. My tortoiſe, which by his conſtant burying himſelf in the earth at the approach of winter, I looked upon as a kind of plant animal, happened to be obſtructed by a vine-root from mining to the depth he was uſually wont to inter, is found ſtark dead, after having many years eſcaped the ſevereſt winter. Of fiſh I have loſt a few, and the nightingales, which for being a ſhort winged bird, and ſo exceedingly fat at the time of the year, we commonly ſuppoſe them to change the climate, whereas indeed they are then hardly able to fly an hundred yards, are as briſk and frolic as ever; nor do I think they alter their ſummer ſtations whatever may become of them all the winter."

In the reign of James II. Mr. Evelyn was, during the abſence of the earl of Clarendon in Ireland, made one of the commiſſioners for executing the office of lord privy ſeal, and after the revolution he was appointed treaſurer of Greenwich hoſpital. In 1697 he publiſhed a diſcourſe on medals, entitled "Numiſmata, &c." and his laſt work was "Acetaria, a Diſcourſe of Sallets," in which he treats of the nature and properties of all plants which have been employed as ſallad herbs. This diſcourſe was inſcribed to lord chancellor Somers. The dedication, which is written with much elegance, was intended to procure, if poſſible, a public eſtabliſhment for the Royal Society. Mr. Evelyn died in Feb. 1706 in his 86th year, having paſſed his days in uſeful and elegant purſuits, and diſtinguiſhed by benevolence, piety, and integrity. Biog. Brit.

Evelyn, John, ſon to the former, was born Jan. 14, 1654, at his father's houſe at Deptford. He was at a very early age admired for his rapid progreſs in knowledge, ſo that in the year 1666 he was ſent to Oxford under the ſpecial care of Dr. Bathurſt, till he could be admitted a gentleman commoner, which was in the Eaſter term, 1688. It does not appear that he took his degrees there, but returned to his father's houſe, where he proſecuted his ſtudies with much diligence and ſucceſs. During his reſidence in Trinity college, he is ſuppoſed to have written the elegant Greek poem which is prefixed to the ſecond edition of the Sylva. He became deeply learned in the ancient and modern languages, and cultivated poetry, of which there is evidence by a tranſlation "Of Gardens, firſt written in Latin by Renatus Rapinus." This was publiſhed when the tranſlator was a youth of nineteen years of age only. He afterwards tranſlated Plutarch's life of Alexander the Great from the Greek; and from the French he gave a tranſlation of "The Hiſtory of the Grand Viziers, Mahomet, and Achmet Coprogli." He was likewiſe author of ſeveral poems, two of which have been chiefly admired, the one "On Virtue," and the other was entitled "The Remedy of Love," and have been inſerted in Dryden's Miſcellanies. Mr. Evelyn was a man of buſineſs as well as a cultivator of literature, and was appointed one of the commiſſioners of the revenue of Ireland. He died in the prime of life, in London, March 24, 1698, in the forty-fifth year of his age, leaving behind him two ſons and three daughters. Biog. Brit,

EUE'MBOLOS, (from *ευ. well*, *εν*, *in*, and *βαλλω*, *to caſt*,) a perſon ſkilful in ſetting bones.

EVEN Foot, in *Poetry*. See Foot.

Even *number*, is that which may be divided into two equal parts or moieties. See Number.

EVENELADS, in *Geography*, a river of England, in the county of Oxford, which runs into the Iſis, about 5 miles W. of Oxford,

EUENES, a town of Norway, 18 miles N. of Drontheim.

EVENING Star, in *Aſtronomy*. See Vesper.

Evening *iſland*, in *Geography*, a ſmall iſland in the Pacific ocean. N. lat. 2° 46'. W. long. 133° 17'.

EVENLY *even number*, is that which is exactly diviſible by an even number taken an even number of times; ſuch is 32, ſince it is diviſible by 8, taken four times.

Evenly *odd number*, is that which an even number meaſures by an odd one; as 30, which is meaſured by 6, taken five times.

EVENUS, in *Ancient Geography*, a river of Aſia Minor, according to Pliny, who ſays that the towns of Lyrneſſa and Miletus were built upon its banks. The inhabitants of Adramyttium drew water from this river by means of canals. Strabo.

Evenus, *Fidari*, a river of Greece, in Ætolia, which took its riſe towards the north-eaſt in mount Pindus, on the frontiers of Theſſaly, and paſſing through the territories of the Bomiæi, Ophienſes, and Apodoti, watered Calydon, and diſcharged itſelf into the ſea; to the weſt is the town called Chalcis. It was on the banks of the Evenus that Hercules, according to the fable, ſlew the centaur Neſſus.

EVERARD'S *ſliding rule*. See Sliding.

EVERBODE, in *Geography*, a town of France, in the department of the Dyle; 5 miles N. of Dieſt.

EVERDINGEN, Cæsar Van, in *Biography*, a painter of hiſtories, portraits, and landſcapes, born at Alkmaer in 1606. The maſter under whom he ſtudied, Van Bronkhorſt, ſoon obſerved and encouraged his ſuperior talents from among the reſt of his diſciples. He had a lively invention, and painted with freedom and firmneſs, and a good force of colouring.

Many of his pictures are ſpoken of in terms of praiſe; but the one ſelected as his principal performance is the repreſentation of the victory of David over Goliath. It was painted on the folding doors of the organ in the great church at Alkmaer; and the ſketch of it was preſerved in the council chamber of that city; it was painted in 1648. He died in 1679, aged 73.

Everdingen, Aldret Van, a landſcape painter, whoſe merit was very conſiderable. He was the nephew of Cæſar Van Everdingen, and was born in the ſame city, Alkmaer, in 1621. Having firſt attended to the inſtructions of Roland Savery, he afterwards greatly improved by thoſe of Peter Molyn; whom at laſt he ſurpaſſed in ſkill. He delighted moſt in the grand ſcenes of nature, or rather her more romantic features, ſuch as rocks, torrents, and cataracts, which he executed with great freedom and variety of touch. In his time he had no ſuperior, but Jacob Ruyſdael followed him immediately, was indeed partly contemporary with him, and in his own ſtyle left him far behind in the brilliancy and force of his colours and execution, and the choice of his forms. However, Everdingen is highly deſerving of great praiſe for the care which he took to make himſelf acquainted with the effects of nature, and the truth with which he marked them. He made a voyage up the Baltic, and was much gratified by and made much uſe of the ſcenery, which the romantic coaſts of that ſea, and of Norway, (which he alſo viſited) afforded him. He died in 1675, and left behind him a great number of drawings, both of real views and compoſitions, which are very freely wrought. He was thought not to ſucceed ſo well in large works as in ſmaller ones, thoſe coming more within the management of the neatneſs of pencilling, which characterizes his ſtyle of execution. The latter are very highly and very deſervedly valued in Flanders and Holland.

Everdingen, in *Geography*, a town of Holland, in Guelderland; three miles W. of Culemburg.

EVERET'S Bridge, a place of Nanſemond county, in Virginia; where is a poſt-office; 266 miles from Waſhington.

EVERGEM, a town of France, in the department of the Eſcaut, and chief place of a canton in the diſtrict of Gand. The place contains 6878, and the canton 13,176 inhabitants, on a territory of 67½ kiliometres and four communes.

EVERGETÆ, in *Ancient Geography*, a people of Aſia, placed by Strabo in the vicinity of Drangiana.

EVERGETES, Ευεργετης, a Greek term, ſignifying *benefactor*, being formed of ευ, *bene*, *well*, and εργον, *opus*, *work*. It is ſtill retained in our language by way of addition or epithet given to two princes or kings of Syria and Egypt, who ſucceeded Alexander. Thus we ſay Ptolemy Evergetes, king of Egypt, Antiochus Evergetes king of Syria.

EVERGREEN Thorn, in *Gardening*. See Mespilus *Pyracantha*.

Evergreen *Trees*, are ſuch trees, whether of tall or ſhrubby growth, as conſtantly retain their leaves during the whole year. There is a great number of this ſort of plants,

plants, which will be particularly deſcribed under their proper genera.

Theſe kinds of trees, ſhrubs, &c. are increaſed in different modes, according to their particular nature, as by ſeeds, layers, cuttings, ſuckers, &c. which is fully ſhewn under the culture of the different ſorts, but principally in the ſpring ſeaſon, though occaſionally in the ſummer, and frequently in the early autumn.

The proper ſeaſons for planting them out are the early autumn or latter ſpring months, according to the nature of the ſoil. Where the ſoils are of the more ſtiff, retentive, moiſt kind, the more advanced ſpring months are the beſt; but where they are of the light, dry, looſe deſcription, the beginning of the autumn is the moſt proper period; as in the former caſe the plants will be in no danger of being injured by ſtagnant moiſture in the winter, and in the latter there will be no riſk of their being deſtroyed by the heat and dryneſs of the ſummer, before they become perfectly eſtabliſhed in the ground.

In the planting of evergreen trees, it is ſeldom neceſſary to put them into any great depth, as they are very liable to be deſtroyed by deep planting. There is likewiſe another circumſtance that ought to be regarded, which is that of having the mould in which they are to be ſet ſufficiently fine, and the roots well bedded in it, without being too much cut in or retrenched. In all caſes the looſe mould ſhould be well trodden in about them; and the more tall growing kinds well ſupported with ſtrong ſtakes, ſo as to keep them perfectly ſteady in their ſituations. Numbers of trees of this, as well as other ſorts, are deſtroyed for want of attention in this reſpect, as when once they get looſe they ſoon die by the motion which takes place. The pruning or cutting in of this ſort of trees, where it is neceſſary, ſhould be performed either in the more advanced ſpring ſeaſon, or the latter part of the ſummer, but never in the winter ſeaſon, as they are liable to much injury from cold. This is equally neceſſary to be regarded in the clipping of hedges conſtituted of plants of this ſort.

Many of theſe ſorts of trees and ſhrubs are ſufficiently hardy to admit of being planted in moſt ſorts of ſoils and ſituations. The tall-growing kinds are well adapted for affording ornament and variety in mixture with thoſe of the deciduous claſs in extenſive plantations, and ſuch as are of a ſhrubby growth in the borders, clumps, and other parts of ornamented grounds. In theſe ſituations they ſhould be ſuffered as much as poſſible to take their natural growth, eſpecially the fir kinds, and in the others only very little cut in, and the dead wood removed from them.

In the forming of hedges various plants of this ſort are employed; but the beſt are thoſe of the holly, yew, evergreen privet, and box kind; though the common laurel and lauruſtinus may be the moſt adviſeable, where they are required to be lofty. Theſe are likewiſe capable of being trained ſo as to cover naked walls, palings, or other unpleaſant objects. Hedges formed of theſe plants ſhould be clipped once or twice during the ſummer ſeaſon, ſo as to keep them in perfect neat order.

Various ornamental devices were formerly made with theſe and other ſorts of evergreens in gardens; but theſe are at preſent little in uſe, as a better and leſs troubleſome taſte prevails.

It has been remarked by the author of "The Philoſophy of Gardening," that in theſe ſorts of trees and ſhrubs the buds riſe in the boſoms of the leaves, which, as they are not ſhed in the autumn, continue to oxygenate the juice of the plants, and ſupply nutriment to the buds during the fine days in the winter and ſpring ſeaſons, ſurviving till nearly the middle of ſummer, when the new buds have expanded leaves of their own. It is hence conjectured, that evergreens provide no ſtore of nouriſhment in their roots, or alburnum in the ſummer for the ſupport of their enſuing vernal buds, and of courſe have probably no bleeding ſeaſon, as is the caſe with thoſe of the deciduous kind.

And there is another circumſtance which has been ſtated by Dr. Milne, in his botanical dictionary, to take place in reſpect to evergreen trees, which is, that when they are engrafted on thoſe of the deciduous ſort, it determines the latter to retain their leaves. This is aſſerted to be confirmed by repeated experience, in grafting the laurel, (*lauro-ceraſus*) an evergreen, on the common cherry, (*ceraſus*), and the (*ilex*), an evergreen oak, on the common oak. And it is probable that many other facts of the ſame kind may exiſt, though they have not been noticed by common gardeners.

EVERLASTING. See Gnaphalium.

Everlasting *Pea*. See Lathyrus.

Everlasting *Pea*, in *Agriculture*, is the common name of a perennial plant of the vetch kind, which grows naturally in ſome ſituations in this country; and is capable of being cultivated with great care and advantage as a green food for cattle or other ſtock, where the ſoils are inclined to be of the more heavy loamy kinds; as it affords a large produce of the moſt nutritious ſort of fodder. Where it is ſuffered to ſtand till the ſeeds are formed, it has been found in the few trials that have been made with it to poſſeſs a highly fattening property when conſumed by animals.

EVERRIATOR, derived from *ex* and *verro*, *I cleanſe*, in *Antiquity*, an officer who was obliged in a ſolemn manner to cleanſe ſuch houſes as were defiled by dead bodies, called *domus funeſtæ*.

EVERRICULUM, (from *everro*, *to ſweep away*,) a kind of inſtrument, in *Surgery*, reſembling a ſpoon, and uſed for taking away any ſmall fragments of the ſtone, which may remain behind in the bladder, in the operation of lithotomy.

EVERS, in *Rural Economy*, a term ſometimes provincially applied to thoſe ſtiles which open; in which caſe the top rail has a bolt of iron driven through it at one end, the other falling into a notch in the oppoſite poſt, by which contrivance an opening can occaſionally be readily made.

EVERSBERG, in *Geography*, a town of Germany, in the kingdom of Weſtphalia; 34 miles N. of Cologn.

EVERY Year's-Land, in *Agriculture*, is a term applied to ſuch lands as have been cropped with what are termed brown and white crops, or pulſe and grain crops, in alternation or ſucceſſion for a very great length of time, without the intervention of any ſort of fallow. Mr. Marſhall has remarked that extenſive common fields in Glouceſterſhire have been conducted under this ſort of management for "perhaps centuries:" and the ſame is the caſe in ſome other countries.

EVES-Droppers, in *Law*. See Eaves-droppers.

EVESHAM, or Esam, in *Geography*, is a borough and market town, pleaſantly ſituated upon a riſing ground, above the banks of a navigable river, named the Warwickſhire Avon, in the hundred of Blakenhurſt, and county of Worceſter, diſtant from London ninety-ſix miles. This place claims high antiquity, and is not leſs notable for its ſubſequent celebrity. The firſt notice of it upon record, like the origin of moſt towns referable to the Saxon period, is the account of Egwin, biſhop of Worceſter, having founded a monaſtery here in the year 709: and amply endowed it by the aſſiſtance of Kenred, ſon of Wulpher, king of Mercia. This was one of the mitred abbies; its abbot ſat in the houſe of peers as a baron of the realm; its privileges were numerous and extenſive, and the revenues on the diſſolution were valued at the annual ſum of 1183*l.* Of the building, which from records appears to have been immenſe, few veſtiges remain. The large elliptical arch, decorated with rich but mutilated imagery, is ſtill ſtanding; and the tower noticed by Leland. "Clement Lichfeild the laſt abbot of Eveſham ſave one, did very much coſt in buildinge of the abbey and other places longing to it.—He made a right ſumptuouſe and high ſquare towre of ſtone in the cemitery of Eoveſham. This tower had a great bell in it, and a goodly clocke, and was as a gateway to one piece of the abbey." Itinerary, vol. iv. p. 108. This tower is a regular and beautiful ſtructure, twenty-two feet by twenty-two, and one hundred and ſeventeen in height; and is generally conſidered the laſt monaſtic building erected under papal influence in England. Though the churches have towers, this ſtill continues the ſtation for the clock and bells.

In that part of the town called Bengeworth, which may be viewed as a ſuburb on the eaſtern ſide of the river, over which the communication is formed by a handſome ſtone bridge of ſeven arches, ſtood an ancient caſtle, probably erected ſoon after the Norman conqueſt. For in the year 1152, abbot William de Audville gained this fortreſs from lord William de Beauchamp, who held it for king Stephen, razed it level with the ground, and converted the ſite into a place of interment.

Eveſham is a very ancient borough, enjoying numerous privileges, both by preſcription and charter. It was one of the towns ſummoned by writ to ſend members to parliament, in the twenty-third year of king Edward the Firſt's reign, when he baſely pretended to reſtore the Saxon conſtitution; and was one of the eight boroughs which had their elective franchiſe reſtored in the time of James the Firſt. That monarch at the ſame time granted a charter to the town to be governed by a mayor, ſeven aldermen, twelve burgeſſes, and twenty-four aſſiſtants, recorder, chamberlain, who are alſo of the common council, and other ſubordinate officers. The mayor and four ſenior aldermen are juſtices of the peace, form a *quorum*, and have power to hold a ſeſſions of *oyer* and *terminer*, and gaol delivery, to puniſh all crimes, except high treaſon, and execute felons within their liberty.

The town is much altered ſince Leland viſited it; the houſes, which then were what are called *half-timbered*, that is, timber frames, having the open parts filled up with wattle and dab, are moſtly well built with brick, the ſtreets are wide and ſpacious, and the ſalubrity of the air, with the beauty of the ſituation, induce many genteel families to take up their reſidence here. In the town are three pariſh churches, two in the part uſually called Eveſham, and one in Bengeworth; a well endowed free grammar ſchool, charity ſchool, and alms-houſe. The market, held on Mondays, is well ſupplied, and four annual fairs are held Febuary the ſecond, the firſt Monday after Eaſter, Whit-Monday, and the twenty-firſt of September. From the late returns to government under the Population act, the number of houſes appear to be 616, and of inhabitants 2837. The richneſs of the ſoil in the vicinity has been long an inducement to turn many of the fields into garden ground, and the peculiar fineneſs of the vegetable productions of this place has rendered Eveſham gardeners proverbial for unrivalled ſkill. They not only ſupply the neighbourhood, but alſo the city of Worceſter, fourteen miles diſtant; Birmingham, thirty; and during the aſparagus ſeaſon Bath and Briſtol, more than fifty. Tindal's Hiſtory and Antiquities of Eveſham.

Evesham, *Vale of.* The fine tract of land comprized under this denomination, unrivalled in fame or fertility, is ſituated on the eaſtern and weſtern banks of the river Avon, extending for ſeveral miles in various directions into Warwickſhire, where it is bounded by the high land of the Ridgeway, and into Glouceſterſhire, where the Cotſwold hills form a terminating barrier; and the ſouth is waſhed by the river Severn.

It is deſcribed in Monaſtic hiſtory as having derived the name, which it gives to the town already deſcribed, from *Eoves*, a Saxon, ſwine-herd to Egwin biſhop of Worceſter, in the latter end of the ſeventh century: this ham having been Egwin's property till he was dethroned by the pope, and his eſtates confiſcated. Previouſly to this it was called Heth-holme, or Heath-field.

To thoſe who wiſh to ſee what "ſun and ſoil," unaſſiſted by art, can do, parts of this diſtrict will furniſh ſtriking ſpecimens. And to the admirers of agriculture other portions will evince what wonders may be effected from aiding the efforts of nature by the application of art. The ſoil is principally a deep heavy loam, or rich loamy clay, of inexhauſtible depth, equally calculated for corn, or paſturage. And whether it be placed under an arable, or a grazing ſyſtem, the produce and the profits alike exceed analogical belief. The vale of Eveſham, ſays Leland, "is, as it were, for ſuch an angle, the horreum of Worceſterſhire, it is ſo plentiful of corn;" and juſtly has he characterized this prolific ſpot. For the abundance of herbage is not equalled by the famous Tilney ſneeth in the hundred of Marſhland and county of Norfolk; nor can the crops of corn be ſurpaſſed, except by thoſe deſcribed in Brydone's Tour as produced in the vales of Sicily. The rent of lands in the farms of this diſtrict is equal to that of accommodation lands in moſt other parts of the kingdom; yet perſons who have occupied eſtates in ſome others, at an exceeding low rate on a compariſon of the net proceeds from both, do not heſitate in deciding in favour of the higher rental. In this vale, about a mile diſtant from the town of Eveſham, was fought the moſt memorable battle recorded in the annals of Engliſh hiſtory, between Simon de Montfort, the powerful earl of Leiceſter, and prince Edward, afterwards king Edward the Firſt; in which the earl was completely defeated, and the refractory barons, with moſt of their adherents, taken or ſlain. He has been not unaptly compared to the Roman conſpirator Catiline, for, like him, he verified in his conduct the remark of Tiberius, recorded in Tacitus Ann. l. iv. c. 18. "Beneficia eo uſque lata ſunt, dum videntur exſolvi poſſe." "Favours are only ſo long properly beſtowed as there appears a probability, or at leaſt a capability of return." After king Henry the Third had conferred upon him an accumulation of honours and emoluments, and even permitted him to marry the princeſs, his ſiſter; he experienced from the earl the moſt ungrateful requital. He purſued the monarch with the moſt inveterate hatred; and by inflammatory ſpeeches, and other overt acts, excited the moſt perplexing commotions, and diſtreſſing inteſtine warfare, the kingdom ever experienced; under a pretence of reſtraining the prerogative, reforming the government, and aſcertaining and ſecuring the liberties of the ſubject. The conteſt, however, was productive of good, intended by neither of the parties. The prince, when he had aſcended the throne, determined to ſtill further curtail the enormous power of the barons; and by his writs ſummoned together, as his adviſers, repreſentatives from numerous cities and boroughs, as well as counties; the battle of Eveſham therefore may be conſidered "as the origin of our preſent houſe of commons."

Evesham, a townſhip of America, in Burlington county, New Jerſey, ſituated between the forks of Moore's creek, which runs north-weſterly to Delaware-river; 16 miles E. of Philadelphia.

EVESPERIDES, in *Ancient Geography*, a people of Africa, in the maritime part of Libya, to the weſt of the Auſchiſes: whoſe country, according to Herodotus, was ſingularly fertile; whence it has been ſuppoſed that the famous garden of the Heſperides was found in their territory. This name, in its grammatical acceptation, ſignifies Occidentals.

EVESPERIS, a town on the coaſt of Africa, which afterwards took the name of Berenice.

EVEST, in *Geography*, a river of Ruſſia, which runs into the Dwina, near Kreutzburg.

EUEXIA, from ευ, *well*, and εξις, *habit*, in *Medicine*, a good ſound habit of body.

EUFEMIA, St., in *Geography*, a town of Naples, in the province of Otranto, two miles N.N.E. of Aleſſano. —Alſo, a town of Naples, in Calabria Ultra, ſituated on a bay of the Mediterranean, to which it gives name. N. lat. 39° 2′. E. long. 16° 30′.

EUFRA, a town of South Finland; 12 miles N.N.E. of Abo.

EUGALENUS, Severinus, in *Biography*, a phyſician of Doccum, in Frieſland, known chiefly as the author of a treatiſe on the ſcurvy, which once maintained a conſiderable character, and paſſed through many editions. Its title is "De Scorbuto Liber, cum Obſervationibus quibuſdam, brevique et ſuccinctâ cujuſque curationis indicatione, 1604." But the treatiſe of Dr. Lind, on the ſame ſubject, in which the abſurdities and ignorance of Eugalenus are pointed out, has ſuperſeded it. Eloy. Mangeti Bibl. Script. Med.

EUGANEI, in *Ancient Geography*, a people of Italy, towards the Alps.

EUGANO, in *Geography*, a mountain of Italy, in the weſt part of the Paduan, bordering on the Vicentin.

EUGENE, Francis, of Savoy, in *Biography*, generally denominated prince Eugene, grandſon of Charles-Emanuel, duke of Savoy, was born at Paris in 1663, and deſtined for the church. His mother, on account of her ill-conduct, was obliged to leave Paris. She retired to Bruſſels, and young Eugene being deprived of her ſupport, and having been diſappointed in his expectations of preferment, went as volunteer to ſerve in Germany againſt the Turks. He, with other French volunteers, was recalled on pain, in caſe of diſobedience, of perpetual baniſhment. He ſet the order at defiance, and ſo much diſtinguiſhed himſelf in his firſt campaign, that the emperor gave him a regiment. After the ſiege of Vienna was raiſed, he ſerved in Hungary under the command of the duke of Lorrain and the elector of Bavaria. From this time his reputation increaſed, with every action in which he engaged, till, in the year 1697, he was appointed to the command of the imperial army. In the autumn of this year he entirely defeated the Turks at the battle of Zeuta, in which the grand vizier and more than 20,000 men were left on the field, and the grand ſeignior was obliged to make a precipitate retreat with the broken relics of his army. Eugene had hazarded this engagement contrary to the expreſs orders of the imperial court; but he ſo completely juſtified his conduct, that Leopold gave him a written authority to act thenceforth according to his own judgment. He was now oppoſed by all the great French generals, but in every battle his exertions and proweſs were crowned with ſucceſs, and on returning to Vienna the emperor created him preſident of the council of war, and entruſted the military cheſt to him; but that cheſt was frequently ill ſupplied, which occaſioned him more trouble than the moſt vigorous oppoſition in the field. He was ſtrictly united with the duke of Marlborough, and by their talents and concert they obtained a deciſive ſuperiority over the French in Germany. At the celebrated battle of Blenheim, Eugene commanded the imperial part of the army, and had no ſmall ſhare in the ſucceſs. In 1705, he was defeated in Italy, but in the following campaign he regained his reputation by marching acroſs Lombardy in the face of the French army, and attacking the French in their intrenchments at Turin, over whom he obtained a complete victory, which ſecured the duke of Savoy and reſtored all the Milaneſe to the emperor. In 1707, he invaded France, but without obtaining any deciſive advantage, and in 1708 he was with the duke of Marlborough at the battle of Oudenard, and the capture of Liſle. He commanded the centre at the bloody battle of Malplaquet, where he was grievouſly wounded, but refuſed to retire from the field, ſaying, "Of what uſe will it be if we are to die here;—if we are to ſurvive it will be time enough in the evening to be dreſſed." When the politics of England took a turn and peace was determined on, Eugene carried on the war alone, till it was concluded by the peace of Radſtadt in 1714. Shortly after this he was called on to contend again with the Turks, whom he ſignally defeated in the year 1716. In the following year he undertook the ſiege of Belgrade, when the Turks came to its relief, and inveſted him in his camp. He ſuffered them to approach very near, and then ſuddenly quitting his lines fell upon them with ſo much vigour, that he killed 20,000 men, and poſſeſſed himſelf of their cannon and camp equipage. Belgrade immediately ſurrendered, and an advantageous peace was the reſult of this important victory. Eugene now retired to Vienna covered with glory, and juſtly conſidered as the ſaviour of the empire, and the greateſt benefactor to the houſe of Auſtria. He was great in retirement, as he had been heroic and magnanimous in war. In the year 1733 he attempted new exploits, in conſequence of the diſputed election to the Poliſh crown; but he was no longer the great, the enterprizing Eugene. He died in 1736 at Vienna, aged ſeventy-three. As a man he was cold and reſerved in his manner, and ſerious in his aſpect: as a friend he was liberal, free from pride, faithful to his promiſes, and ever ready to do a kind action. As a general he was regarded by thoſe under him in the character of a father and protector: in his military capacity he was enterpriſing, full of reſources, and though he ſometimes committed faults, he rarely failed to redeem his credit by new and brilliant ſucceſſes. Moreri. Modern Univerſal Hiſt. Hiſt. of England. See alſo the article Churchill in this Dictionary.

EUGENIA, in *Botany*, ſo named by Micheli in compliment to the heroic prince Eugene of Savoy, who ſent him from Germany almoſt all the plants deſcribed by Cluſius, and who had a celebrated botanic garden. Mich. Gen. 226. t. 108. Linn. Gen. 247. Sm. Tr. of Linn. Soc. v 3. 280. Schreb. 333. Willd. Sp. Pl. v. 2. 959. Mart. Mill. Dict. v. 2. Juſſ. 324. (Syzygium; Gærtn. t. 33.). Claſs and order, *Icoſandria Monogynia*. Nat. Ord. *Heſperideæ*, Linn. *Myrti*, Juſſ.

Gen. Ch. *Cal.* Perianth ſuperior, in four deep, oblong, obtuſe, concave, permanent ſegments, the orbicular centre between them elevated, and ſomewhat downy. *Cor.* Petals four, twice as large as the ſegments of the calyx, oblong or roundiſh, obtuſe, concave. *Stam.* Filaments numerous, inſerted into the elevated ring of the calyx, about as long as the corolla; anthers ſmall, roundiſh. *Piſt.* Germen inferior, turbinate; ſtyle ſimple, the length of the ſtamens;

ſtigma ſimple: *Peric.* Berry roundiſh or angular, crowned with the calyx, of one cell. *Seed* ſolitary, roundiſh, ſmooth and even.

Eſſ. Ch. Calyx ſuperior, in four deep ſegments. Petals four. Berry of one cell, with one ſeed.

Obſ. The number of petals, and ſegments of the calyx, is frequently five, in one inſtance eight. The germen has, in ſome ſpecies at leaſt, two cells, though one of them becomes obliterated as the fruit ripens.

This is an extenſive genus, chiefly from the Eaſt and Weſt Indies, whoſe ſpecies are as difficult to define as the roſes in our European gardens. Their habit is akin to the myrtle, but often more ſtout and arboreſcent. *Leaves* ſimple, oppoſite, ovate or elliptical, entire, without ſtipulas, moſt frequently ſmooth, paler beneath, evergreen. *Flowers* either terminal or axillary, white or reddiſh. *Fruit* not unwholeſome, but ſcarcely ever very grateful to the palate; in ſome caſes highly fragrant. Willdenow has 30 ſpecies, a number far ſhort of what are known, and yet two of them (*acutangula* and *racemoſa*), are ſcarcely true *Eugeniæ*. There is alſo ſome confuſion between this genus and *Plinia*, the original *E. uniflora*, Linn. Sp. Pl. 673, being not only *Myrtus braſiliana*, ibid. 674, but alſo *Plinia rubra*, Linn. Mant. 243; as well as *P. pedunculata*, Linn. Suppl. 253; under which laſt name it is figured in Curt. Mag. t. 473, with a wrong quotation of Linn. Mant. Whatever the *Plinia* of Plumier may be, this plant is the original *Eugenia* of Micheli's figure, and is well known in the Braſils and Weſt Indies, its fruit reſembling an indifferent cherry in ſize, taſte, and colour, though different in being externally furrowed. This fruit ſometimes ripens in ſtoves in England, but the plant is no general favourite, being a meagre repreſentative of the common myrtle.

E. *Jambos*. Linn. Sp. Pl. 672. (Malacca Schambu; Rheede Hort. Mal. v. 1. t. 17.), is much celebrated for the fragrance of its fruit, which reſembles that of a roſe, or rather roſe-water. It is alſo of an extremely fine yellowiſh colour with a roſy tint, and though not pleaſant to the taſte, is frequently brought to table in the Indies, for the ſake of its perfume.

E. *malaccenſis*. Linn. Sp. Pl. 672. Sm. Exot. Bot. t. 61, a beautiful Eaſt Indian ſpecies, is eſteemed for the elegance of its red cluſtered flowers, as well as the flavour and cooling quality of its fruit.

EUGENIUS I. in *Biography*, pope, was born at Rome, and raiſed to the higheſt dignity in the church in the year 634, on the depoſition of pope Martin. He owed his elevation to the choice of the Roman people and clergy, and their choice was confirmed by the emperor Conſtans. At this period the weſtern and eaſtern churches were furiouſly contending with each other upon the queſtion whether Chriſt poſſeſſed one will or two. Eugenius, after his promotion, took pains to quiet the minds of the diſputants. A compromiſe was entered into between the parties, but it was not of that nature to command general approbation: it was unſatisfactory to the Roman people and clergy, who oppoſed the admiſſion of the patriarch Peter's confeſſion of faith. Peter had taken the other ſide of the queſtion, and in his confeſſion he took no notice of the will and operations in Chriſt. So vehement was this party that they refuſed to permit the pope to perform divine ſervice in the church of St. Mary, until he had publicly declared his condemnation of it. We have no other particulars relating to this pope, who died in the year 657, but he was commended by his contemporaries and ſucceſſors for piety, mildneſs, humanity, and generoſity. Moreri. Bower.

Eugenius II. pope, was a Roman by birth, and from being archprieſt of St. Sabina, was made biſhop of Rome in the year 824. This election was oppoſed by the people, who made choice of a different perſon for pope. The double election excited conſiderable diſturbances at Rome, which occaſioned the interference of Lewis the Debonnaire, who decided for Eugenius, and confirmed him in his high office. The monarch took this opportunity of reviving ſeveral ancient cuſtoms and laws, declaratory of the dependence of the biſhops of Rome on the imperial power, and determining the limits of the ſubmiſſion and obedience which were paid to them. Eugenius, to ſecure his own power, took the oath of fidelity to Lewis and his ſon Lotharius, in which was included their ſolemn engagement that no future pope ſhould be conſecrated with their conſent, but in the preſence of the emperor's deputy, and after the exaction of a ſimilar oath to what was at that time adminiſtered. During the pontificate of Eugenius, a council was aſſembled in France under the auſpices of Lewis and the Greek emperors Michael and his ſon Theophilus, to examine the doctrine of the Greek church, in relation to images. This was in the year 825, and at the concluſion of the council the biſhops wrote a letter to Lewis, giving ſentence againſt both parties, *viz.* the churches of Conſtantinople and Rome; the former for breaking images, whence they were denominated "Iconoclaſtæ," and the latter for worſhipping them, whence they obtained the title of "Iconolatræ," declaring at the ſame time that it was a far greater crime to worſhip than to break images. The emperor was alſo exhorted by the council to interfere with the pope, and to intreat him to aboliſh the ſuperſtitious worſhip of images, which was the cauſe of much offence to all good men. Lewis wrote to the pope, and deputed two biſhops to reaſon with him on the ſubject, but to little or no purpoſe; he continued not only to promote, but to juſtify the practice of image worſhip. In the following year Eugenius held a council at Rome, in which a number of decrees were paſſed, intended to reform the ſtate of eccleſiaſtical diſcipline, and to encourage the progreſs of literature both ſacred and profane, but he died in the year 827, before he could carry his plans into effect. He was highly ſpoken of by Catholic writers, and applauded for his humility, his beneficence, and the humane policy of his government. He is repreſented as excelling in mental and corporeal endowments. As a writer, two of his epiſtles, and eleven of his decrees, are extant in the ſeventh volume of the "Collectio Conciliorum." It has been reported, and not greatly to the credit of Eugenius, that he was the inſtitutor of the ordeal by cold water. See Ordeal. Moreri. Bower.

Eugenius III. pope, ſo called upon his elevation to the popedom, from his uſual name Bernard, was a native of Piſa, and a diſciple of St. Bernard. On the death of Lucius II. in the year 1145, Bernard was unanimouſly fixed on by the cardinals as the new pope, and was enthroned with the uſual ceremony under the title of Eugenius III. The people, who had been long ſtruggling to wreſt from the popes the ſovereignty which they had acquired over them in temporal matters, would not ſuffer Eugenius to be conſecrated, unleſs he reſigned all pretenſions to dominion, otherwiſe than as connected with his ſpiritual rank, and would be contented with the revenue to be derived from tithes, and the voluntary contributions of the faithful. Unwilling to make theſe conceſſions, he privately withdrew to the Benedictine monaſtery of Farſa in Sabina, whither he was followed by the cardinals, and conſecrated. Not daring to return to Rome, he removed from Farſa to Viterbo, where he continued for ſome months. During his abode there embaſſadors arrived from the Cruſaders in the Eaſt, to implore aſſiſtance from the pope and the weſtern princes againſt the Turks, who had gained ſome important advantages over them. Eugenius ſupplicated the aſſiſtance of Lewis VII. king of France, ſtrongly urging him to march in perſon to the relief of the Chriſtians in the Holy Land, and conferring on thoſe who ſhould attend him the privileges which his predeceſſors had granted to ſuch as engaged in the holy war. Lewis embarked, and Eugenius now took meaſures to reduce the Romans to ſubmiſſion, which he effected in a ſhort time, and forced them to acknowledge him as their temporal as well as ſpiritual lord. His triumph was of no long duration, for an inſurrection obliged him to ſeek for perſonal ſafety in flight. He went to Treves, where he held a council in the year 1146. In the following year he was reſpectfully entertained at Paris by the king; and here he was allowed to hold a council, in which William, archbiſhop of York, was depoſed from his dignity. From Paris he went to Rheims, where, in 1148, he held that council before which the fanatic Eon was examined. See Eon. He next returned to Italy, and, with the aſſiſtance of the king of Sicily, once more ſubdued the people of Rome, in the year 1149. Shortly after this he was obliged to retire into Campania, where he remained till the year 1152. During this period he was not inactive, but ſent a legate into Ireland, by whom he eſtabliſhed the four archbiſhoprics in that kingdom. He was now permitted to return to Rome, where he lived in peace till his death in 1153. His virtues have been highly commended by his contemporaries. By ſome writers his chief merit ariſes from his zeal and ſufferings in promoting the intereſts of the holy ſee, and in combating the errors of heretics: by more modern hiſtorians his memory has been held in abhorrence on account of the active part which he took in promoting the Cruſades, by which great calamities overwhelmed Europe and the eaſtern world. Moreri. Bower. See Croisade.

Eugenius IV. pope, was a native of Venice, and of plebeian rank, though deſcended from an ancient family. His original name was Gabriel Condelmerio, and while he was very young he accompanied a nephew of pope Gregory XII. to Rome, where he took the Celeſtine habit. He was afterwards made treaſurer to the pope himſelf, and then biſhop of Sienna. In 1408 he was advanced to the office of cardinal preſbyter of St. Clement. While Martin V. was pope he was ſent delegate into the Marche of Ancona, and afterwards to Bologna, and performed the duties repoſed in him with great ability and reputation. On the death of Martin in 1431, he was elected to the papal ſee, when he aſſumed the name of Eugenius IV. Immediately upon his elevation he involved himſelf, and the city of Rome, in the moſt alarming difficulties, by attempting to ſeize upon treaſures ſaid to have been left by his predeceſſors; and no ſooner was he extricated from the dangers reſulting from this conduct, than he drew upon himſelf freſh troubles with the council of Baſil, which he determined to diſſolve on account of their conciliating meaſures with the Huſſites of Bohemia. His legate, cardinal Cæſarini, whom he empowered to act on the occaſion, a man of much diſcretion, forewarned him of the troubles he was likely to bring on himſelf by the act. Eugenius had, however, made up his mind, and in 1431 iſſued his bull, declaring the council of Baſil to be diſſolved, and appointing another to be convened in eighteen months at Bologna. The emperor urged the pontiff to revoke his decree, ſetting forth in ſtrong and very preſſing terms the evils into which he would otherwiſe plunge the Chriſtian world; and he added that he was ſure the aſſembled biſhops would not ſubmit to be diſappointed of the object of their meeting, and that he, as protector of the church, was bound to afford them his ſupport. Eugenius was immoveable, and the council were alike determined to ſet his power at defiance. After confirming the decrees of the council of Conſtance, which declared the papal power to be ſubordinate to that of a general council, and bound by its ſtatutes and mandates, they voted that no power on earth could diſſolve them without their conſent, and that none ſhould withdraw from them without their leave; and they went ſo far as to ſummon the pope to appear in perſon before them within a limited time, or to ſend legates with full authority to act in his name. The firmneſs of the council, after much altercation, brought the pope to ſubmiſſion, and in the year 1433 he iſſued a bull, declaring null and void whatever had been done by him, or in his name, in derogation of the council-general of Baſil. In the ſame year Eugenius received the emperor Sigiſmond at Rome with great magnificence, and crowned him there. Shortly after this he was attacked by Philip duke of Milan, who laid waſte the territory of Rome, and when the inhabitants laid their complaints before the pope, he referred them to the cardinal his nephew, who, regardleſs of every thing that did not contribute to his own eaſe and pleaſure, treated their ſufferings with neglect and contempt. Enraged at this behaviour they took up arms, and produced a temporary revolution at Rome. It was with the utmoſt difficulty that Eugenius eſcaped from their fury, and took refuge at Florence; a reconciliation was effected, which was farther confirmed through the mediation of the council of Baſil, who diſpatched ſome of their body to offer friendly advice on the occaſion. In 1437 freſh diſſenſions aroſe between the council and the pope, which terminated in their final rupture, and a new council was appointed to meet at Ferrara, whoſe firſt act was to declare the congregation of Baſil an unlawful aſſembly, and themſelves the only oecumenical council lawfully aſſembled, and they ordered all biſhops who ſtill remained at Baſil to withdraw from that city within thirty days, on pain of excommunication, and the forfeiture of their dignities and benefices. The council of Baſil, on the other hand, paſſed a decree or ſentence of ſuſpenſion againſt Eugenius from papal juriſdiction, forbidding all eccleſiaſtics, on pain of excommunication, to obey him. Early in the year 1439, a contagious diſorder breaking out at Ferrara, the pope tranſlated the council to Florence, where a pretended union was effected between the Greek and Latin churches, which, being violently oppoſed at Conſtantinople, was rendered null and void. In the mean time the council of Baſil, after declaring the ſuperiority of councils over the pope to be an article of the Catholic faith, proceeded to depoſe Eugenius from the papacy, as diſobedient to the commands of the church, a contemner of the canons, a diſturber of the unity of the church, and an obſtinate heretic; and they diſpatched nuncios to the different courts of the Chriſtian princes to acquaint them with the meaſures which had been adopted. Eugenius thundered out his excommunications againſt the fathers at Baſil, but they held his decrees in deriſion, and raiſed to the papal throne Amadeus, duke of Savoy, who aſſumed the name of Felix V. The rival popes and rival councils anathematized each other, laying claim to the true apoſtolic powers. Eugenius was ſupported by France, Italy, Spain, Portugal, Hungary, and England, but Felix was defended by the people of Savoy, by the Swiſs, and by the dukes of Bavaria and Auſtria. The German princes choſe to preſerve a neutrality till the year 1447, when they declared for Eugenius, determining that he was the only true vicar of Chriſt upon earth. In the midſt of the public rejoicings on this occaſion, he died in his ſixty-fourth year. His character as a pope is eaſily gathered from what has been ſaid; he was ambitious, intriguing, and a decided enemy to reform. In his laſt illneſs he is ſaid to have been painfully affected with reflections on his paſt life; "Oh Gabriel," exclaimed the dying pontiff, "how much better had it been for thy ſoul's ſafety, hadſt thou never been promoted to the dignity of cardinal or pope!" He was a patron of literature and learned men, though he had no pretenſions to learning himſelf; his epiſtles and bulls are to be found in volumes xii. and xiii. of the "Collectio Conciliorum." He was a handſome man, of a venerable aſpect, and always looked downwards when he appeared in public. He was frugal and temperate in his own perſon, but was liberal and hoſpitable; and at his table there was a princely magnificence. In this reign the cardinals began to indulge in the ſports of the field, and to abandon themſelves to all kinds of luxury. Bayle. Moreri. Bower.

Eugenius, Catholic biſhop of Carthage, was raiſed to that ſituation in the year 481, at the requeſt of the emperor Zeno, who had entered into a treaty of peace with Hunneric, at that time the reigning monarch. In the year 483, he was ſummoned, with the other Catholic biſhops, by the king, to Carthage, to maintain a public debate in defence of their principles againſt the Arian biſhops, whom he patronized. Eugenius undertook to draw up a treatiſe, explanatory of the Catholic faith, which was approved by all the biſhops of his party, and preſented to Hunneric, and he offered to defend the principles contained in it by an appeal to the ſacred writings, as well as to the ſentiments of the fathers. He alſo delivered a petition to that prince, in the form of an apology, the deſign of which was, to obtain peace for the Catholics. It was, however, of no avail; the biſhops of that party were all ſentenced to baniſhment, and Eugenius was ſent into exile, amidſt the dreary deſerts of Tripoli. In the following year Hunneric died, and Eugenius was permitted to return to Carthage, but was again baniſhed, on the acceſſion of Thraſamund, and ſent into Gaul. He died at Albi, in the year 505. His principal works are, "Expoſitio fidei Catholicæ," "Apologeticus pro fide;" "Altercatio cum Arianis;" and a letter to his people, exhorting them to conſtancy in the orthodox faith. Moreri.

Eugenius, biſhop of Toledo, in the ſeventh century, was attached to the monaſtic life, but compelled, by order of the prince, to accept of the epiſcopal dignity in the year 646. He filled that ſee ſeveral years, and made a figure at the councils of Toledo, which were held in the years 653, 655, 656. He was author of a treatiſe "On the Trinity," and two books on miſcellaneous ſubjects. He reviſed and improved Dracontius's work on the creation of the world, which was publiſhed at Paris, together with his "Opuſcula," in the year 1619. Moreri.

EUGHTGUR, in *Geography*, a town of Hindooſtan, in the circar of Kitchwara; 15 miles E. of Ougein.

EUGIA, in *Ancient Geography*, a ſmall country of the Peloponneſus, in Arcadia.

EUGMO, in *Geography*, a ſmall iſland on the eaſt ſide of the gulf of Bothnia. N. lat. 63° 49′. W. long. 22° 42′.

EUGUBIO. See Gubbio.

EUHYDRIUM, in *Ancient Geography*, a town of Greece, in Theſſaly, according to Livy.

EVIAN, in *Geography*, a town of France, in the department of the Leman, on the coaſt of the lake of Geneva, containing two pariſhes and two convents. The place includes 1502, and the canton 12,911 inhabitants, on a territory of 280 kiliometres, and in 19 communes. Near Evian are ſome mineral waters, which render it in ſummer a place of reſort. It is ſituated 23 miles N. E. from Geneva. N. lat. 46° 25′. E. long. 6° 24′.

EVICTION, from *evinco*, *I overcome*, in *Law*, ſignifies a recovery of lands or tenements by law.

EVIDENCE, a quality in things whereby they become viſible and apparent to the eyes, either of the body or the mind.

The ſchoolmen diſtinguiſh evidence into *formal* and *objective*. The former is the act of the intellect, conſidered as clear and diſtinct; the latter conſiſts in the clearneſs and perſpicuity of the object; or it is the object itſelf ſo conſtituted as that it may be clearly and diſtinctly known.

Others divide evidence into *moral*, *phyſical*, and *metaphyſical*. A thing is ſaid to be *morally evident*, ſo far as we have a diſtinct notion or knowledge thereof, by unexceptionable witneſſes; *phyſically*, ſo far as natural ſenſe and reaſon, pointing out any thing, convince us thereof; *metaphyſically*, when we enter fully and clearly into the eſſence of any thing.

Evidence is the eſſential and infallible character or criterion of truth, and is that in effect which with us conſtitutes truth.

If evidence ſhould be found in propoſitions that are falſe, we ſhould be compelled into error, ſince the aſſent we give to evidence is neceſſary: whence would follow this impious poſition, that God who made us is the author of our errors, as he has conſtituted us ſo as to put us under a neceſſity of falling into them.

It may be added that as we neceſſarily love truth and hate error, it ſeems inconſiſtent with the nature of a beneficent being to form us with a love of what we could not obtain, or not know whether we did obtain it or not; beſides, that if we ſhould err in things that are evident, as well as in thoſe that are not ſo, we ſhould ſometimes find contradictions in evident propoſitions, as we commonly do in things that are obſcure.

Evidence, therefore, muſt be allowed the mark of truth; and thoſe things muſt be allowed true which carry with them ſuch a degree of evidence as obliges us to aſſent to them. Whatever we ſee evidently agreeable to things whereof we ſpeak, that we muſt acknowledge to be true.

The Epicureans allow of no other evidence but that of ſenſe, or that ariſing from ſenſe, it being a fundamental principle with them, that ſenſe is the firſt and primary criterion of all truth. By evidence of ſenſe, they mean that ſpecies or image exhibited by the ſenſe or phantaſy; which, when all impediments to a juſt judging, as diſtance, motion, medium, &c. are removed, cannot be contradicted or gainſaid; wherefore, the queſtion being put, whether or not a thing be ſuch as it appears; the anſwer is not to be given, till it has been tried and examined in all the ways, and by all the ſenſes, of which it can be an object. See Error.

There are certainly other ſuperior and leſs fallible ſources or grounds of evidence than ſenſe: ſuch is that inward conſciouſneſs by which we learn what belongs to the mind, or that which Mr. Locke calls reflection; of which ſuch are intelligence, intuition, and common ſenſe, principally relating to thoſe abſtracted, or other propoſitions that carry their own evidence with them, and admit no doubt about them; whence we derive our aſſent to propoſitions called axioms and maxims: ſuch is alſo reaſoning, whereby we infer one truth from others by natural and juſt methods of argument, whence reſults ſcience: ſuch is likewiſe the teſtimony of others, on which we found the evidence of Faith (ſee alſo Testimony): to which we may alſo add inſpiration, or that impreſſion made on the mind by God himſelf, which gives a convincing and indubitable evidence of the truth of any propoſition, and atteſted to others, either by prophecy or miracles. Watts's Logic, part ii. chap. ii. § 9.

By thus conſidering the various ſources whence our perception and belief of any truth are derived, we may be led to diſtinguiſh evidence into intuitive and deductive, and that founded on teſtimony. Intuitive evidence comprehends that of pure intellection, of conſciouſneſs, and of common ſenſe, under the laſt of which that of memory is included. (See INTUITIVE.) Deductive evidence is divided into ſcientific and moral; the latter of which includes thoſe kinds of evidence that are deduced from experience, analogy, and teſtimony, to which may be added a mixed ſpecies, derived from the calculation of chances. (See DEDUCTIVE.) See alſo each of the above-mentioned ſubjects. See Campbell's Phil. of Rhet. book i. chap. 5.

The evidences of the Chriſtian religion are diſtinguiſhed into two kinds, the direct and collateral: the direct evidences are external and internal; the external are miracles and prophecy; the internal evidence is deduced from its excellence, conſidered in reference to the main and principal end of Chriſtianity. Whatever does not either belong to its excellence conſidered in this light, or fall under the head of miracles wrought on purpoſe to atteſt it, or of prophecies fulfilled, and yet affords a proof or any real preſumption of its truth and divinity, is a collateral evidence for it. All the collateral evidences of the truth of Chriſtianity are in one ſenſe internal evidences, becauſe they all ariſe from ſome particulars in the nature of this religion, from ſome circumſtances which have attended its reception, or ſprung from it, or from ſome remarkable facts connected with it, and related in the goſpel hiſtory. Of this kind is the argument deduced from its great efficacy at its firſt appearance, in baniſhing polytheiſm, idolatry, ſuperſtition, and the arts of magic; in ſoftening the rigour of deſpotiſm, introducing moderation into government, excluding many inconvenient civil laws once generally prevalent, giving riſe to others of a very happy tendency, reſiſting the laws of war, humanizing the manners, and improving the cuſtoms of nations, and reforming the temper and conduct of thoſe who embraced it.

Another claſs of collateral arguments for the truth of the Chriſtian religion, ariſes from particulars in its nature or effects produced by it, or from facts in the Goſpel hiſtory, which cannot be at all accounted for but on the ſuppoſition of a Divine original; or which are, at leaſt, moſt naturally explicable on that ſuppoſition. To this claſs may be referred thoſe preſumptive arguments deduced from the character of Jeſus, ſo exalted, and yet ſo uniformly ſupported; the nature of his laſt diſcourſes with his diſciples; the character of ſome of his apoſtles; that of Judas the traitor; the controverſies among Chriſtians in the apoſtolic age; and the method uſed by Chriſt and his apoſtles, of referring their claims to the impartial inquiries of men. Other collateral arguments have an affinity to the external evidences of Chriſtianity: ſuch are thoſe derived from the miraculous converſion of the apoſtle Paul and his ſubſequent conduct; from the character of the man of ſin foretold by Paul; from the quick and extenſive propagation of the Goſpel; from the continuance and preſent ſtate of the nation of the Jews. Some of theſe arguments have an immediate relation to the proof of Chriſtianity from prophecies; others are related to the proof from miracles. Other arguments have an equal relation to the internal and external evidence of Chriſtianity; ſuch is that deduced from the manner in which Chriſt and his apoſtles propoſed the evidences of their miſſion, and the advantage they have gained in conſequence of the oppoſition and ſcrutiny of unbelievers. See on this ſubject Lord Lyttelton's Obſervations on the Converſion and Apoſtleſhip of St. Paul, Duchal's Preſumptive Arguments for the Truth of the Chriſtian Religion, and Gerrard's Diſſertation on the genius and evidences of Chriſtianity.

EVIDENCE, in *Law*, is any proof, whether by teſtimony of men on oath, or by writings and records; the former called *parol evidence*, that is, by word of mouth, and the latter *written evidence*.

It is thus called, becauſe the point in iſſue is hereby made evident to the jury. Evidence in the trial by jury includes not only that which is given in proof, but that which the jury may receive by their own private knowledge; for an account of which ſee the ſequel of this article.

With regard to parol evidence, or witneſſes, we may obſerve in general, that all witneſſes, whatever be their religion or country, that have the uſe of their reaſon, are to be received and examined, except ſuch as are *infamous*, or ſuch as are *intereſted* in the event of the cauſe. All others are competent witneſſes; though the jury from other circumſtances will judge of their credibility. Infamous perſons are ſuch as may be challenged as jurors, *propter delictum*; and, therefore, never ſhall be admitted to give evidence to inform that jury, with whom they were too ſcandalous to aſſociate. Intereſted witneſſes may be examined upon a *voir dire*, if ſuſpected to be ſecretly concerned in the event; or their intereſt may be proved in court. A party intereſted in a ſuit, or a wife for or againſt her huſband, a huſband againſt his wife, except in caſes of treaſon, an alien infidel, perſons *non ſanæ memoriæ*, thoſe that are attainted of conſpiracy, or in a præmunire upon ſtat. 5 Eliz. cap. 1. popiſh recuſants convict on ſtat. 3 Jac. I. cap. 5. (See contra 1 Hawk. P. C. c. 12. § 6.) perſons convicted of felony, perjury, &c. thoſe who by judgment have ſtood on the pillory, or been whipped, whilſt the judgment is in force, are diſabled from giving evidence: but kinſmen, though ever ſo near, tenants, ſervants, maſters, attornies for their clients, but not againſt them, becauſe they are obliged to keep their ſecrets, one of the jurors upon trial, and all others that are not infamous, who want not underſtanding, or are no parties in intereſt, may give evidence in a cauſe, though the credit of ſervants is left to the jury. (2 Rol. Abr. 685. 1 Vent. 243.) If after a man hath ſtood in the pillory, &c. he be pardoned, he may be an evidence; and though judgment of the pillory infers infamy at common law, by the civil and canon law it imports no infamy, unleſs the cauſe for which the perſon was convicted was infamous; and, therefore, ſuch may be a good witneſs to a will, if not convicted of any infamous act. (3 Lev. 426, 427.) It has been held, that it is not ſtanding in the pillory which diſables a perſon for giving evidence; but ſtanding there upon a judgment for an infamous crime, as forgery, &c. If for a libel, a man may be a witneſs. (5 Mod. 74. 3 Nelſ. Abr. 557.) Perſons excommunicated cannot be witneſſes; but perſons outlawed may be witneſſes, becauſe the outlawry has no influence on their credibility. (Bull. N. P. 292, 3.) A man convicted of felony, and afterwards pardoned, may be a good evidence. (Raym. 369.) Burning in the hand is ſaid to reſtore a perſon to his credit. (Ibid. 330.) A perſon condemned to be hanged for burglary, but having a pardon for tranſportation, hath been allowed to be a good evidence. (5 Mod. 108.) One outlawed for treaſon and pardoned may be an evidence. (State Trials, vol. iii. 515.) Perſons acquitted, or guilty of the ſame crime, while they remain unconvicted, may be evidence againſt their fellows. (Kel. 17.) Although no evidence ought to be given of what an accomplice hath ſaid, who is not in the ſame indictment; (State Trials, vol. ii. 414.) an informer may be a witneſs, though he is to have part of the forfeiture, where no other witneſſes can be had. (Wood's Inſtit. 598.) If an action is brought againſt many perſons for taking of goods, one of them may be admitted as an evidence againſt the reſt. (Comberb. 367. 1 Mod. 282.) In criminal caſes, as of robbery on the high way, in action againſt the hundred; in rapes of women, or where a woman is married by force, &c. a man or a woman may be an evidence in their own cauſe. (1 Vent. 243.) And in private enormous cheats, a perſon may give evidence in his own cauſe, where nobody elſe can be a witneſs of the circumſtances of the fact but he that ſuffers. (1 Salk. 286.) Upon an information on the ſtatute againſt uſury, he that borrows the money, after he hath paid it, may be an evidence, but not before. (Raym. 190.) Although an alien infidel may not be an evidence, a Jew may, and be ſworn on the Old Teſtament. (1 Inſt. 6.) A quaker ſhall not be an evidence in any criminal cauſe unleſs he will take an oath: though on other occaſions his affirmation ſhall be accepted inſtead of an oath. Stat. 7 and 8 W. III. c. 34. See QUAKER.

The oath of a Gentoo, ſworn according to the circumſtances of his religion, has been admitted in a civil matter. (1 Atk. 21.) And by Willes C. J. an infidel in general is an admiſſible witneſs, for the term does not imply that he is an atheiſt; but whenever it appears that a witneſs hath no idea of a God or religion, he ſhall not be permitted to give his teſtimony. (1 Atk. 40. 45.) When perſons that are competent witneſſes are ſerved with a writ of *ſubpœna ad teſtificandum*, they are bound to appear at the trial on pain of 100*l.* to be forfeited to the king, to which the ſtat. 5 Eliz. cap. 9. has added a penalty of 10*l.* to the party aggrieved, and damages equivalent to the loſs ſuſtained by want of their evidence: but no witneſs, unleſs his reaſonable expences be tendered him, is bound to appear at all; nor if he appears, is he bound to give evidence till ſuch charges are actually paid him, except he reſides within the bills of mortality, and is ſummoned to give evidence within the ſame. In a criminal cauſe, if a witneſs refuſe to appear, and give evidence, being ſerved with proceſs, the court will put off the trial, and grant attachment againſt him; and as refuſing to give evidence is a great contempt, the party may be committed and fined. (1 Salk. 278.) Preventing evidence to be given againſt a criminal is puniſhable by fine and impriſonment; and perſons diſſuading a witneſs from giving evidence, &c., and jurors or others, diſcloſing evidence given, are likewiſe offences puniſhed in the ſame manner. (2 Hawk. P. C. c. 22.) Members of either houſe of parliament may be witneſſes on impeachments. (State Trials, vol. ii. 612.) A perſon who hath a legacy in a will, is not a good witneſs to prove the will; but if he releaſe his legacy, he may be a good evidence. (Skin. 704.) Thus alſo, a perſon who claims any benefit by a deed, may not be an evidence to prove that deed; and a perſon concerned in the ſame title of land in queſtion will not be admitted as evidence. (Ibid. 705.) If a legatee is permitted to be ſworn and examined, the counſel cannot afterwards except againſt his evidence. (1 Lord Raym. 730.) To obviate all difficulties, it is enacted by ſtat. 25 Geo. II. c. 6. that any deviſe to a perſon being witneſs to any will or codicil ſhall be void, and ſuch perſon ſhall be admitted as a witneſs; and that any creditor atteſting a will or codicil, by which his debt is charged upon land, ſhall be admitted as a witneſs to the execution, notwithſtanding ſuch charge: the credit of every ſuch witneſs being left to the conſideration of the court and jury. The ſon of a legatee is no witneſs to a will in the ſpiritual court; but it is held he may be a good evidence to prove a nuncupative will, within the intent of the ſtatute of frauds. (1 Lord Raym. 85.) See WILL.

One credible witneſs is ſufficient evidence to a jury of any ſingle fact in all civil actions, though the concurrence of two or more corroborates the proof; but in caſes of high-treaſon, petit-treaſon, and miſpriſion of treaſon, by ſtatutes 1 Edw. VI. cap. 12. 5 and 6 Edw. VI. cap. 11. and 1 and 2 Ph. and Mar. cap. 10. *two* lawful witneſſes are required to convict a priſoner, except in caſes of coining and counterfeiting the ſeals, or unleſs the party ſhall willingly and without violence confeſs the ſame: and by ſtat. 7 W. III. cap. 3. the confeſſion of the priſoner muſt be in open court; and both witneſſes muſt be to the ſame overt-act of treaſon, or one to one overt-act, and the other to another overt-act of the ſame ſpecies of treaſon. Baron Monteſquieu, indeed, lays it down for a rule, Spirit of Laws, book xii. chap. 3. that thoſe laws which condemn a man to death *in any caſe*, on the depoſition of a ſingle witneſs, are fatal to liberty.

All evidence is to be given in open court, in the preſence of the parties, their attornies, the counſel and all by-ſtanders, and before the judge and jury: many advantages attend this way of giving teſtimony, *ore tenus*, a method familiar among the ancient Romans, as may be collected from Quintilian, Inſt. Orat. lib. v. cap. 7. and it was continued as low as the time of Adrian; but the civil law, as it is now modelled, rejects all public examination of witneſſes.

No witneſs is bound to give any anſwer by which he confeſſes or accuſes himſelf of any crime. The court in criminal caſes is to examine the witneſſes, and not the priſoner or proſecutors. A witneſs ſhall not be permitted to read his evidence, but he may look at his notes to refreſh his memory. A witneſs may not recite his evidence to the jury, after having gone from the bar, and he hath given his evidence in court; if he does, the verdict may be ſet aſide. (Cro. Eliz. 159.) One that is to be an evidence at a trial, ought not to be examined before the trial, but by the conſent of both parties, and a rule of court for that purpoſe. No evidence ought to be produced againſt a man, in a trial for his life, but what is given in his preſence. State Trials.

Poſitive proof is always required whenever the nature of the caſe poſſibly admits of it.

Sometimes violent preſumption will be admitted for evidence without witneſſes; as where a perſon is run through the body in a houſe, and one is ſeen to come out of the houſe with a bloody ſword, &c. but on this the court ought not to judge haſtily, 1 Inſt. 6. 673; and though preſumptive and circumſtantial evidence may be ſufficient in felony, it is not ſo in treaſon. State Trials.

Though all preſumptive evidence of felony ſhould be admitted cautiouſly, for the law holds that it is better that ten guilty perſons eſcape, than that one innocent ſuffer. (See PRESUMPTION.) Sir Matthew Hale lays down two rules, moſt prudent and neceſſary to be obſerved. 1. Never to convict a man for ſtealing the goods of a perſon unknown, merely becauſe he will give no account how he came by them, unleſs an actual felony of ſuch goods be proved: and, 2. Never to convict any perſon of murder or manſlaughter, till at leaſt the body be found dead; on account of two inſtances, which he mentions, where perſons were executed for the murder of others, who were then alive, but miſſing. 2 Hal. P. C. 200.

Evidence by writings and records, is where acts of parliament, ſtatutes, judgments, ſines, and recoveries, proceedings of court, and deeds, &c. are admitted as evidence. The printed ſtatute-book is good evidence upon a general act of parliament, which need not be pleaded; but in the caſe of a private act, it is otherwiſe; for there it muſt be pleaded and examined by the records of parliament before it can be admitted in evidence. Records and enrolments prove themſelves; and a copy of a record or enrolment, ſworn to, may be given as an evidence. (Co. Litt. 119. 262.) A record of an inferior court has been rejected in evidence; and the proceedings in county-courts, courts-baron, &c. may be denied, and then tried by a jury. But court-rolls of a court-baron, when ſhewn, are good evidence; and, in many caſes, copies of the court-rolls are allowed as evidence. An ancient deed of thirty years ſtanding proves itſelf; but modern deeds, and other writings, muſt be atteſted and verified by parol evidence of witneſſes. The counterpart of a deed is no evidence, when the original is in being, and can be procured; though it may be, when the original cannot be procured. (Co. Litt. 225. 10 Rep. 92.) The counterpart of an ancient deed hath been admitted as evidence. (Mod. Caſ. 225.) In caſe of a fine, a counterpart is good evidence of itſelf. (1 Salk. 287.) Although a witneſs ſwear to the hand and contents of a letter, if he never ſaw the party write, it will not be good evidence. If all the witneſſes to a deed are dead, continual and quiet poſſeſſion is preſumptive evidence of the truth of it; yet it may receive farther credit by compariſon of hands and ſeals. (Wood's Inſt. 599.) When witneſſes to deeds are dead, their hand-writing muſt be proved. (2 Inſt. 118.) If one of ſeveral witneſſes ſurvive, a ſubpœna muſt be taken out againſt the living witneſs, and ſtrict inquiry made after him, and affidavit made that he cannot be found, before the hand-writing of the deceaſed witneſſes is to be proved. (1 Litt. 556.) And a ſhop-book may not be given in evidence for goods ſold, &c. by 7 Jac. I. cap. 12. after one year, before the action brought, except there be a bill, &c. for the debt; unleſs between merchant and merchant in the uſual intercourſe of trade. In order to make books evidences, if the ſervant who was accuſtomed to make entries in it be dead, his hand muſt be proved; and this, when accompanied with other collateral proofs of fairneſs and regularity, is the beſt evidence that can then be produced. In debt, a releaſe may be given in evidence; ſo may any matters of fact, tampering with witneſſes, or fraud.

In order to prove a leaſe for years, nothing ſhall be admitted but the very deed of leaſe itſelf, if in being; but if that be poſitively proved to be burnt or deſtroyed, then an atteſted copy may be produced, or parol evidence given of its contents. No evidence of a diſcourſe with another will be admitted, but the man himſelf muſt be produced: yet in ſome caſes, as in proof of any general cuſtoms or matters of common tradition or repute, the courts admit of *hearſay* evidence, or an account of what deceaſed perſons have declared in their life-time; but ſuch evidence will not be received of any particular facts. The probate of a will, when it concerns merely perſonal eſtate, may be given in evidence; but where title of lands is claimed under a will, the original will muſt be ſhewn, not the probate, though if the will be proved in the Chancery, copies of the proceedings there will be evidence. (2 Rol. Abr. 687. Trials per pais, 234. 1 Salk. 286. Raym. 335.) In ſome caſes the ledger-book of the eccleſiaſtical court in which the will is entered is ſufficient evidence, being a roll or record of the court. (Bull. N. P. 245, 6.) Depoſitions of witneſſes in Chancery between the ſame parties may be given as evidence at law, if the witneſſes are dead, and the bill and anſwer proved. Depoſitions before a coroner are admitted as evidence, the witneſſes being dead, or gone beyond ſea. (1 Lev. 182. 2 Nelſ. Abr. 760.) The confeſſion of a priſoner before a magiſtrate, &c. may be given in evidence againſt him. (See 2 Hawk. P. C. c. 46.) See Baron Gilbert's Treatiſe of Evidence, or the Introduction to the Law of Niſi Prius, 4to. 1767.

From this treatiſe the following rules of evidence are extracted. 1. In general, the beſt evidence muſt be given that the nature of the thing will admit of. 2. No perſon intereſted in the queſtion can be a witneſs. To this rule there are ſome exceptions; as, 1. A party intereſted may be admitted in a criminal proſecution in moſt inſtances. 2. He may be admitted for the ſake of trade in the common uſage of buſineſs, as porters, apprentices, &c. 3. Where no other evidence is reaſonably to be expected. 4. Where he acquires his intereſt by his own act, after the party who calls him as a witneſs has a right to his evidence. 5. Where the poſſibility of intereſt is very remote. 3. The third general rule is that hearſay is no evidence. 4. In all caſes where a general character or behaviour is put in iſſue, evidence of particular facts may be admitted; but not where it comes in collaterally. 5. In every iſſue the affirmative is to be proved. 6. No evidence need be given of what is agreed by the pleadings, &c. &c. See PLEADING.

Sir Thomas Smith reſtrains evidence to authentic writings of contracts, written, ſealed, and delivered. De Rep. Ang. lib. ii.

EVIDENCE, *demurrer to.* See DEMURRER.

EVIDENCE, *exception to.* See EXCEPTION.

EVIL, MALUM, in *Ethics*, a privation or abſence of ſome proper or neceſſary good, or of ſome meaſure or degree thereof.

Evil is either *natural* or *moral;* between which there is this relation, that moral evil produces natural.

EVIL, *moral*, is defined a deviation from right reaſon; a diſcernment of right from wrong, being given us as a guide of our actions; or it is the diſagreement between the actions of a moral agent and the rule of thoſe actions, whenceſoever it is derived, and howſoever made known; and no action can be morally evil unleſs the agent be properly ſuch, intelligent and free, and capable of diſtinguiſhing, chooſing, and acting for himſelf. This the philoſophers call *inhoneſtum*, and *turpe*, as ſtaining the image of God, and ſullying our original beauty; likewiſe *malum culpæ*.

EVIL, *natural*, is a want of ſomething neceſſary to the *bene eſſe*, or perfection of a thing, or to its anſwering all its purpoſes; ſuch are defects of the body, blindneſs, lameneſs, hunger, diſeaſes, death. This ſpecies is denominated *triſte*, *injucundum*, *noxium*, and *malum pœnæ*.

Good and evil, ſays a learned writer, are oppoſites, and ariſe from the relations which things have to each other: for ſince there are ſome things which profit, and others which prejudice one another; and ſince ſome things agree, and others diſagree; we call the former good and the latter evil. Whatever, therefore, is incommodious or inconvenient to itſelf or any thing elſe; whatever becomes troubleſome or fruſtrates any appetite implanted by God; whatever forces any perſon to do or ſuffer what he would not, that is *evil.* Theſe inconveniencies appear to be of three kinds: thoſe of imperfection; thoſe that are natural; and thoſe that are moral. By the evil of imperfection we may underſtand the abſence of thoſe perfections or advantages which exiſt elſewhere, or in other beings; by natural evil, pains and uneaſineſſes, inconveniencies and diſappointments of appetites ariſing from natural motions; and by moral evils, vicious elections, that is, ſuch as are hurtful to ourſelves, or others. This opinion is otherwiſe ſtated in the following manner: all evil is inconveniency, but ſome inconveniencies ariſe from the ſeries of natural cauſes without our conſent, and ſometimes our knowledge; theſe we call natural evils: but others happen from the abuſe of elections, when an undue choice occaſions them; and in this caſe, beſides the natural evil that ariſes from them, there is likewiſe an obligation on the perſon that makes the choice to anſwer for the hurt he has done by it. Now theſe choices that bring inconveniencies are called moral evils; and the difference between natural and moral evil is not their both bringing inconveniencies and injury to ourſelves or others, for this conſtitutes the nature of their evil, but that the ill effects of the one proceed from the choice, thoſe of the other from natural cauſes; and hence the author of that choice is anſwerable for the one, but nobody for the other. Moral evil, therefore, is natural evil, with choice ſuperadded. See archbiſhop King's "Eſſay on the origin of Evil," by Law, vol. i. and ii. Sherlock, alſo, in his "Treatiſe on Judgment," p. 20, &c. diſtinguiſhes in a ſimilar manner between moral and natural good and evil; the only difference between them, he ſays, is this, "that moral good and evil is in the will and choice, natural good and evil is in the nature of things; that which is good or hurtful to ourſelves or others is naturally good or evil; to love, to chooſe, to do that which is good or hurtful to ourſelves or others, is morally good or evil, or is the good or evil of our choice or actions. If you will but recollect yourſelves, you will find that you have no other notion of good or evil but this; when you ſay ſuch a man has done a very good or very evil action, what do you mean by it? Do you not mean, that he has done ſomething very good or very hurtful to himſelf or others? When you hear that any man has done good or evil, is not the next queſtion, what good or what hurt has he done? And do not you mean by this, natural good or evil? which is a plain evidence that you judge of the moral good or evil of actions by the natural good or evil which they do."

The ingenious author of the "Enquiry into the Origin of our Ideas of Beauty and Virtue," gives the following ſtatement of the nature of moral good and evil, and of the difference between theſe and natural good and evil. Moral evil, according to this philoſopher, denotes our idea of a quality apprehended in actions which excites averſion and diſlike towards the actor, even from perſons who receive no diſadvantage thereby; as moral goodneſs denotes our idea of a contrary quality which procures approbation and love towards the actor, even in perſons unconcerned in its natural tendency. This notion ſuppoſes an univerſally acknowledged difference of moral good and evil from natural. Moral good, we all know, procures love towards thoſe we apprehend poſſeſſed of it; whereas natural good does not. How differently, for inſtance, are we affected towards thoſe we ſuppoſe poſſeſſed of honeſty, faith, generoſity, &c. when we expect no benefit from thoſe qualities, and thoſe poſſeſſed of the natural goods, as houſes, lands, gardens, health, ſtrength, &c. So whatever quality we apprehend morally evil, raiſes our hatred towards the perſon in whom we obſerve it; as treachery, cruelty, ingratitude, &c. whereas we love and pity many expoſed to natural evils, as pain, hunger, ſickneſs, &c.

The origin of theſe different ideas of actions has greatly puzzled the moraliſts: ſome make ſelf-intereſt, or ſelf-love, the ſource of them all; we approve the virtue of others as it has ſome ſmall tendency to our happineſs, either from its own nature, or from this general conſideration, that a conformity to nature and reaſon is in the general advantageous to the whole, and to us in particular; and on the contrary, diſapprove the vice of others, as tending at the long run to our particular detriment.

Others ſuppoſe an immediate natural evil in the actions called *vicious*, that is, that we are determined to perceive ſome deformity or diſpleaſure in ſuch actions, without reflecting on any diſadvantage that may any way redound to us from the action; and that we have a ſecret ſenſe of pleaſure accompanying ſuch of our own actions as are called *virtuous*, when we expect no farther advantage from them; but then they add, that we are excited to perform thoſe actions, even as we purſue or purchaſe pictures, ſtatues, landſcapes, &c. from ſelf-intereſt, to obtain the pleaſure which accompanies the action.

But the author juſt mentioned maintains that ſome actions have to men an immediate goodneſs, and others an immediate evil, *i. e.* we perceive pleaſure in ſome and pain in others, and are determined to love or hate the doers, without any view of natural advantage, without any view to future rewards or puniſhments, or even without any intention to obtain the ſenſible pleaſure of the good, but from a very different principle, *viz.* an internal moral ſenſe, or a natural determination of the mind to receive amiable or diſagreeable ideas of actions, when they ſhall occur to our obſervation, antecedently to any opinion of advantage or loſs to redound to ourſelves from them, even as we are pleaſed with a regular form or an harmonious compoſition, without any knowledge of the mathematics, or ſeeing any advantage in that form or compoſition different from the immediate pleaſure. But according to this account of Dr. Hutcheſon, however plauſible, moral good and evil ſignify nothing in the objects themſelves, to which they are applied, any more than agreeable and harſh, ſweet and bitter, &c. but only certain effects in us; and virtue is a mere affair of taſte; whereas it ſeems to be much more juſt to conclude, that right and wrong, or good and evil, are real qualities of actions, and not merely of our minds; and that the power whereby we perceive theſe qualities is not any arbitrary ſenſe but the underſtanding: or to ſuppoſe with another excellent writer, that moral good, conſidered as ſynonymous with virtue, denotes the doing good to mankind, in obedience to the will of God, and for the ſake of everlaſting happineſs, and moral evil or vice, the contrary. Price's Original of our Ideas, &c. p. 13, and p. 59, &c. Paley's Principles of Moral and Political Philoſophy, vol. i. p. 41. See farther under DEFORMITY, SENSE, GOOD, VIRTUE, and VICE.

The queſtion concerning the origin of evil has very much perplexed philoſophers and divines, both ancient and modern. Plato, for the ſolution of this queſtion, maintained, that matter, from its nature, poſſeſſes a blind and refractory force, from which ariſes in it a propenſity to diſorder and deformity; and that this is the cauſe of all the imperfection which appears in the works of God, and the origin of evil. Matter, he conceives, reſiſts the will of the ſupreme artificer, ſo that he cannot poſſibly execute his deſigns; and this is the cauſe of the mixture of good and evil, which is found in the material world. "It cannot be," ſays he, (Theæt. t. i. p. 176.) "that evil ſhould be deſtroyed, for there muſt always be ſomething contrary to good;" and again, "God wills, *as far as it is poſſible*, every thing good, and nothing evil." What is that property of matter which oppoſes the wiſe and benevolent intentions of the firſt intelligence, Plato has not clearly explained, but he ſpeaks of it as Ξύμφυτος ἐπιθυμία, an innate propenſity to diſorder, (Phileb.) and ſays, "that before nature was adorned with its preſent beautiful forms, it was inclined to confuſion and deformity, and that from this habitude ariſes all the evil which happens in the world." Plutarch ſuppoſes the Platonic notion to be, that there is in matter an unconſcious irrational ſoul; and this ſuppoſition has been adopted by ſeveral modern writers. But the writings of Plato afford no evidence, that he conceived the imperfection of matter to ariſe from any cauſe diſtinct from its nature. Such a notion is incongruous with Plato's general ſyſtem, and it is contrary to the doctrine of the Pythagorean ſchool, to which he was probably indebted for his notions on this ſubject; for the philoſophers of that ſect held, that motion is the effect of a power eſſential to matter. Some of the Stoics adopted the notion of the Platoniſts concerning the origin of evil, and aſcribed it to the defective nature of matter, which it is not in the power of the great artificer to change; aſſerting, that imperfections appear in the world, not through any defect of ſkill in its author, but becauſe matter will not admit of the accompliſhment of his deſigns. But it was perceived by others, that this hypotheſis was inconſiſtent with the fundamental doctrine of the Stoics concerning nature. For ſince, according to this ſyſtem, matter itſelf receives all its qualities from God, if its defects be the cauſe of evil, theſe defects muſt be ultimately aſcribed to him. No other way of relieving this difficulty remained, but to have recourſe to fate, and ſay, that evil was the neceſſary conſequence of that eternal neceſſity, to which the great whole, comprehending both God and matter, is ſubject. Thus, when Chryſippus was aſked, whether diſeaſes were to be aſcribed to divine Providence, he replied, that it was not the intention of nature that theſe things ſhould happen; nor were they conformable to the will of the author of nature and parent of all good things; but that, in framing the world, ſome inconveniences had adhered, by neceſſary conſequence, to his wiſe and uſeful plan. To others the queſtion concerning the origin of evil appeared ſo intricate and difficult, that finding themſelves unequal to the ſolution of it, they denied either that there is any God at all, or, at leaſt, any author or governor of the world. The Epicureans belonged to this claſs; nor does Lucretius allege any other reaſon for denying the ſyſtem of the world to be the production of a deity beſides its being ſo very faulty. Others again judged it to be more rational to aſſign a double cauſe of viſible effects than to aſſign no cauſe at all; as nothing, indeed, can be more abſurd than to admit actions and effects without any agent and cauſe. Theſe perſons, perceiving a mixture of good and evil, and being perſuaded that ſo many inconſiſtencies and diſorders could not proceed from a good being, ſuppoſed the exiſtence of a malevolent principle, or God, directly contrary to the good one; hence they derived corruption and death, diſeaſes, griefs, miſchiefs, frauds and villanies, whilſt from the good being they deduced nothing but good. This opinion was held by many of the ancients; by the Perſian magi, Manichæans, Paulicians, &c. &c. See theſe articles, and alſo ZOROASTER. Abſurd as this hypotheſis was, it very long and generally prevailed, not only in the Heathen but in the Chriſtian world; nor have the light and influence of Chriſtianity yet availed to its total extermination, ſo that no trace or remnant of it remains. Thoſe who wiſh to find a ſatisfactory refutation of it, may conſult "King's Origin of Evil," vol. i. and the annexed notes of the editor.

The excellent Dr. Clarke, in his "Demonſtration of the Being and Attributes of God," deduces from the poſſibility and real exiſtence of human liberty an anſwer to the queſtion, what is the cauſe and original of evil? "For liberty," he ſays, "implying a *natural* power of doing evil, as well as good; and the imperfect nature of finite beings, making it poſſible for them to abuſe this their liberty to an actual commiſſion of evil; and it being neceſſary to the order and beauty of the whole, and for diſplaying the infinite wiſdom of the Creator, that there ſhould be different and various degrees of creatures, whereof, conſequently, ſome muſt be *leſs perfect* than others; hence there neceſſarily ariſes a poſſibility of evil, notwithſtanding that the Creator is infinitely good. In ſhort thus: all that we call *evil*, is either an *evil of imperfection*, as the *want of certain faculties and excellencies which other creatures have*; or *natural evil*, as *pain*, *death*, and the like; or *moral evil*, as all kinds of *vice*; the *firſt* of theſe is not properly an evil. For every power, faculty, or perfection, which any creature enjoys, being the free gift of God, which he was no more obliged to beſtow, than he was to confer being or exiſtence itſelf; 'tis plain the want of any certain faculty or perfection in any kind of creatures, which never belonged to their nature, is no more an evil to them, than their never having been created or brought into being at all, could properly have been called an evil. The *ſecond* kind of evil, which we call *natural evil*, is either a neceſſary conſequence of the former; as *death*, to a creature on whoſe nature immortality was never conferred; and then 'tis no more properly an evil than the former; or elſe 'tis counterpoiſed, in the whole, with as great or greater good; as the *afflictions and ſufferings of good men*; and then alſo it is not properly an evil; or elſe, laſtly, 'tis a *puniſhment*; and then 'tis a neceſſary conſequent of the *third* and laſt ſort of evil, *viz. moral evil*. And this ariſes wholly from the abuſe of *liberty*, which God gave to his creatures for other purpoſes, and which 'twas reaſonable and fit to give them for the perfection and order of the whole creation: only they, contrary to God's intention and command, have abuſed what was neceſſary for the perfection of the whole, to the corruption and depravation of themſelves. And thus all ſorts of evils have entered into the world, without any diminution to the infinite goodneſs of the Creator and Governor thereof.

EVIL, or *King's* **EVIL**, the appellation formerly given to *ſcrofula*, in conſequence of the ſuppoſed power poſſeſſed by the kings of England and France of curing this diſeaſe by *touching* the ſick.

The origin and firſt exerciſe of this royal faculty are not agreed upon by hiſtorians; thoſe of France are diſpoſed to maintain, that it was originally inherent in their kings, ſome aſſerting that St. Louis, others that king Robert, was the firſt who was thus gifted; but by moſt other writers it is aſſigned as an earlier prerogative of the Engliſh crown. Edward the Confeſſor is generally mentioned as the firſt poſſeſſor of this miraculous power: and it was diſputed in the days of Malmſbury, who lived not long after his reign, whether this faculty were a peculiar reward from heaven for that king's ſanctity, or hereditarily reſident in the Engliſh crown. Polydore Virgil has noticed this gift to Saint Edward, and its continuance in the line of his ſucceſſors; and Dr. Harpsfield, in his Eccleſiaſtical Hiſtory of England, after deſcribing the miracles of the Confeſſor, obſerves, "quam ſtrumoſos ſanandi admirabilem dotem in poſteros ſuos Anglorum reges, ad noſtra uſque tempora transfudiſſe et perpetuaſſe, merito creditur." The practice was long continued, and ſeems to have reached its greateſt height in the reign of Charles II. to whom multitudes flocked to receive the benefits of the royal touch; inſomuch, that after his reſtoration, he is ſaid to have laid his hands upon more than ſix thouſand perſons in one year. His majeſty was therefore obliged to make ſome reſtrictions with regard to the times of healing, and the number of patients. All perſons were obliged to go to the king's ſurgeon, whoſe duty it was to examine their certificates from the miniſter and church-wardens of their pariſh, to determine whether they were proper objects, to give them tickets of admiſſion to the royal preſence, and to introduce every one to the king's ſacred hand to be touched. The king uſually gave public notice of the day of healing; in the winter the ceremony was always held at Whitehall; in the ſummer ſometimes at Whitehall, and ſometimes at Windſor.

The following curious paragraphs were made public in 1660.

"The kingdom having been for a long time troubled with the evil, by reaſon of his majeſty's abſence, great numbers have lately flocked for cure. His ſacred majeſty, on Monday laſt, touched 250 in the Banqueting houſe; among whom, when his majeſty was delivering the gold, one ſhuffled himſelf in, out of an hope of profit, which had not been ſtroked, but his majeſty quickly diſcovered him, ſaying, this man hath not yet been touched. His majeſty hath for the future appointed every Friday for the cure, at which 200, and no more, are to be preſented to him, who are firſt to repair to Mr. Knight, the king's ſurgeon, &c. Parliamentary Journal, July 2—9, 1660.

"Saturday being appointed by his majeſty to touch ſuch as were troubled with the evil, a great company of poor afflicted creatures were met together, many brought in chairs and flaſkets; and being appointed by his majeſty to repair to the Banqueting-houſe, his majeſty ſat in a chair of ſtate, where he ſtroked all that were brought to him, and then put about each of their necks a white ribbon, with an angel of gold on it. In this manner his majeſty ſtroked above ſix hundred; and ſuch was his princely patience and tenderneſs to the poor afflicted creatures, that though it took up a very long time, his majeſty, who is never weary of well-doing, was pleaſed to make inquiry whether there were any more that had not yet been touched. After prayers were ended, the duke of Buckingham brought a towel, and the earl of Pembroke a baſon and ewer, who, after they had made obeiſance to his majeſty, kneeled down till his majeſty had waſhed." Mercurius Politicus, June 21—28, 1660.

An exact regiſter was at that time kept of the number of caſes that came for relief, and the whole amount is very great. From 1660 to 1664 incluſive, a period of five years, 23,601 perſons were touched by Charles II.: and from May 1667 to May 1684, the number of perſons touched amounted to 68,506; making all together 92,107. For the intervening years, 1665 and 1666, no regiſter was made, the king having removed from the metropolis on account of the plague.

This ſuperſtitious practice was dropped by the preſent royal family, "who obſerved (ſays Hume) that it could no longer give amazement, even to the populace, and was attended with ridicule in the eyes of all men of underſtanding." Rapin indeed remarks, that "the late king William III. of glorious memory, was ſo perſuaded he ſhould do no injury to perſons afflicted with this diſtemper, by *not* touching them, that he refrained from it all his reign." The practice continued in vogue in the reign of queen Anne; it is recorded of Dr. Johnſon, that he was touched by that princeſs, but without effect.

It is extraordinary that this belief in the efficacy of the royal touch in the cure of this ſevere diſeaſe was by no means confined to the vulgar, nor to perſons unacquainted with the nature and cure of diſeaſes. Dr. Johnſon's mother is ſaid to have been inſtigated by the advice of a celebrated phyſician, ſir John Floyer, to bring her ſon to London for the purpoſe of receiving the remedy. And Wiſeman and Browne, eminent ſurgeons of their day, and ſurgeons to the king (Charles II.) have given their ſtrongeſt teſtimony in favour of the ſuperiority of the royal remedy, over any which their art poſſeſſed. "I muſt needs profeſs," ſays Wiſeman, "that what I write will do little more than ſhew the weakneſs of our ability, when compared with his majeſty's, who cureth more in any one year, than all the chirurgeons of London have done in an age. However, that this attempt may not ſeem to want precedent, give me leave to tell you, that it is no more than the French kings' chirurgeons have done before me, or than old Mr. Clows did in queen Elizabeth's days, and all other general writers in chirurgery have done more or leſs." And he affirms that he had been "a frequent eye-witneſs of many cures performed by his majeſty's touch alone, without any aſſiſtance of chirurgery; and thoſe many of them ſuch as had tired out the endeavours of able chirurgeons before they came thither."

The other ſurgeon royal juſt mentioned has left us the moſt circumſtantial account of this royal healing, in a publication, entitled "Adeno-choiradelogia; or, an Anatomick-Chirurgical Treatiſe of Glandules and Strumæs, or King's-evil-ſwellings, together with the Royal Gift of Healing, or Cure thereof, by Contact or Impoſition of Hands, performed for above 640 years by our kings of England; continued with their admirable effects and miraculous events; and concluded with many wonderful examples of Cures by their ſacred touch. All of which are ſuccinctly deſcribed by John Browne, one of his Majeſty's Chirurgeons in Ordinary, and Chirurgeon of his Majeſty's Hoſpital, London, 1684." His offices evince that the author was a man of character, and his book is approved, as was the cuſtom of his time, by the preſident and ſeveral fellows of the College of Phyſicians. Like Wiſeman, he ſeems to have been a ſtaunch loyaliſt, and a vehement defender of the divine right of kings; he deteſted all diſſenters, and confidently aſſerts that the uſurper, Cromwell, tried in vain to exerciſe this royal prerogative, "he having no more right to the healing power, than he had to the regal juriſdiction." The third part of the treatiſe of Browne, which is devoted to the hiſtory and nature of the royal gift, is entitled *Chariſma Baſilicon*. Beſides an hiſtorical view of this prerogative, it contains rules for the meaneſt capacity to find out the diſeaſe, which were deemed expedient to prevent poor people from unneceſſary journeys; and ſixty admirable cures, performed with or without gold, are circumſtantially detailed, as well as ſeveral caſes of ſcrofulous tumours and ſores, which diſappeared on being touched with handkerchiefs dipped in the blood of Charles I.

Some ſhrewd ſuſpicions had, indeed, been thrown out, that the piece of gold, given by the king on the occaſion, was the moſt efficacious remedy employed; and the above mentioned writers are anxious to refute ſuch a ſlander on the royal qualifications. The author of a late treatiſe tells the following ſtory, which may, in ſome degree, account for the numbers regiſtered at Whitehall. "An old man, who was witneſs in a cauſe, had by his evidence fixed the time of a fact, by queen Anne having been at Oxford, and touched him while a child, for the cure of the *evil*. When he had finiſhed his evidence, the relator had an opportunity of aſking him whether he was really cured. Upon which he anſwered, with a ſignificant ſmile, that he believed himſelf never to have had a complaint, that deſerved to be conſidered as the *evil*; but that his parents were poor, *and had no objection to the bit of gold*." See Wiſeman's Chirurgical Treatiſes, book iv. chap. 1. Browne above cited. Edin. Med. and Surg. Journal, vol. iii. p. 185.

With reſpect to the nature of the diſeaſe, vulgarly called *King's Evil,* and the practice now adopted for its cure, ſee Scrofula.

EULEPA, in *Ancient Geography,* a town of Cappadocia. Itin. Anton.

EULER, Leonard, in *Biography,* a great mathematician, was born at Baſil in the year 1707, where he was educated. He performed his academical taſks with ſo much rapidity, that he had a good portion of time left at his own command, which he conſecrated to the ſtudy of the mathematics. In the purſuit of this kind of knowledge, he was aſſiſted by John Bernouilli, who was regarded as one of the chief mathematicians of Europe, and whoſe diſtinguiſhed attention and eſteem he obtained, by his early proficiency and unwearied application. In 1723, M. Euler was admitted to the degree of M. A. on which occaſion he obtained great applauſe by delivering a Latin diſcourſe, wherein he drew a compariſon between the philoſophy of Newton and the Carteſian ſyſtem. In compliance with his father's deſire, he applied himſelf to theology and oriental literature, in which he made no inconſiderable progreſs, but his predominant bias ſtill leading him to the mathematics, his father allowed him to follow the bent of his inclination. In the courſe of his ſtudies under Bernouilli, he contracted an intimate friendſhip with his two ſons, Nicholas and Daniel, which proved to be of the higheſt advantage to him in after life. Thoſe two celebrated mathematicians having been invited to Peterſburgh, in the year 1725, by Catharine I. for carrying into execution the project of Peter the Great, for the eſtabliſhment of an academy of ſcience, promiſed Euler to uſe their endeavour to find him a ſituation in that city. By their advice he applied himſelf diligently to the ſtudy of natural knowledge, and attended the lectures of all the eminent profeſſors of Baſil. While engaged in theſe purſuits he compoſed a diſſertation "On the nature and propagation of Sound;" and alſo an anſwer to a prize queſtion, "Concerning the maſting of Ships," which obtained the ſecond prize. By this circumſtance his attention was early drawn to the curious and important ſtudies of naval architecture and navigation, which he contributed greatly to enrich in the ſubſequent periods of his life. He now joined his friends the Bernouillis at Peterſburgh, and was appointed with them a joint profeſſor in the univerſity of that city. In this ſituation his talents and genius were ſo far called into exerciſe as to entitle him to rank among the moſt eminent mathematicians. He contributed many memoirs to the academical collection, which excited a noble ſpirit of emulation between him and his two friends, unalloyed by the leaſt mixture of envy or jealouſy, and ſuch as produced no alteration in their friendſhip. The integral calculus he carried to new degrees of perfection; invented the calculation of ſines; ſimplified analytical operations, and in this way threw new light on all the branches of mathematical ſcience. In 1730, M. Euler was appointed profeſſor of natural philoſophy; and, in 1733, he ſucceeded his friend Daniel Bernouilli, in the mathematical chair. In 1735, the academy propoſed an intricate and important problem for ſolution, which Euler completed in three days, though it was ſuppoſed to be the labour of many months. The exertion on this occaſion was ſo violent that it produced a fever which endangered his life, and deprived him of the uſe of one of his eyes. In the year 1740, the Academy of Sciences at Paris propoſed for ſolution the important ſubject of "The flux and re-flux of the ſea." To this Euler applied the force of his genius, and produced a memoir, which was allowed to be a maſter piece of analyſis and geometry. He had, however, as competitors, Daniel Bernouilli, and our countryman, Colin Maclaurin, with whom he ſhared the prize. In 1741, Euler, at the expreſs invitation of the king of Pruſſia, repaired to Berlin, where his induſtry and talents appeared to great advantage. He furniſhed many eſſays for the memoirs of the Pruſſian academy, without withholding his contributions from the academy of Peterſburgh, which was now encouraged by the patronage and munificence of the empreſs Elizabeth. In 1742, he obtained a penſion from the academy at Peterſburgh, and in 1766, by permiſſion of the king of Pruſſia, he returned to that city, to ſpend the remainder of his days, when the munificence of Catharine II. liberally rewarded him for the preference which he exhibited towards his Peterſburgh connections. Shortly after his return he loſt the ſight of the other eye, yet in this deplorable ſituation he dictated to his ſervant, an unlettered youth, and who was entirely unacquainted with mathematical knowledge, his "Elements of Algebra," a work of high merit, and which has been tranſlated into the Engliſh language. At this period he was elected one of the very few foreign members of the Academy of Sciences at Paris. After this he received from them the prize for his diſſertations "Concerning the inequalities in the motions of the planets:" alſo two prizes for queſtions propoſed relative to "A more perfect theory of the moon." He next reviewed his whole theory with the aſſiſtance of his ſon, and Meſſrs. Krafft and Lexell; and purſued his reſearches till he had conſtructed the new tables which appeared with the great work in 1772. "This work alone," ſays his biographer, "would be ſufficient to render his name immortal, and when it is conſidered that it was completed after he was totally blind, and at a time in which he was embarraſſed in his domeſtic circumſtances by a dreadful fire, that had conſumed great part of his ſubſtance, and forced him to quit the ruined houſe; it is impoſſible not to be ſtruck with admiration and aſtoniſhment at the powers of his genius and memory, and the perſeverance, fortitude, and tranquillity of mind which he muſt have poſſeſſed." Some time after this he underwent the operation of couching, which reſtored to him his ſight; but either too eager to benefit by the organ, or by the negligence of his ſurgeon, he was a ſecond time deprived of his ſight, and the relapſe was attended with much tormenting pain. Still he was active in the purſuit of ſcience, and in the courſe of ſeven years tranſmitted to the academy of Peterſburgh ſeventy diſtinct memoirs, and left behind him two hundred more, which were afterwards reviſed and completed. In the beginning of September, 1783, he was ſeized with ſeveral attacks of a vertigo; theſe, however, did not prevent his calculating the motion of air-balloons, which then began to engage the attention of the philoſophical world; but on the 7th of the ſame month, while he was amuſing himſelf with his grand-children, an apoplectic fit terminated his illuſtrious career, at the age of 76. Beſides being foreign member of the Royal Academy of Sciences at Paris, M. Euler was member of the Imperial Academy of Peterſburgh, ancient director of the Royal Academy of Berlin, and fellow of the Royal Society of London. His works were very numerous; his knowledge was not conſined to his favourite ſtudies of the mathematics and aſtronomy, of which he has ſecured to himſelf an imperiſhable fame. He had made much progreſs in medical, botanical, and chemical ſcience. He alſo poſſeſſed, in a high degree, what is generally called erudition. He had read with attention and taſte the moſt eminent Latin claſſics, and was familiarly acquainted with the civil and literary hiſtory of all ancient and modern nations. His uncommon memory ſeemed to retain every idea that was conveyed to it either from reading or from meditation. The Æneid of Virgil he could repeat from the beginning to the end, and point out to his hearers the firſt and laſt line of every page in the edition which he uſed. He enjoyed a vigorous conſtitution, and a ſurpriſing ſhare of health, conſidering the intenſity and ardour of his application. His manners were unaffected and pleaſing, his temper lively and cheerful, and his converſation both inſtructive and entertaining. The evening of his days was calm and ſerene, ſweetened in no ſmall degree by the fame that follows genius, the univerſal eſteem and reſpect that were due to his exemplary virtues, and the ſatisfaction which he received from the kind offices of friendſhip, and the endearments of domeſtic felicity.

This great geometrician had beſtowed much meditation, early in life, on harmonics, or the philoſophy of ſound; for in 1739, at the age of 32, he publiſhed at Peterſburgh, in Latin, a work in 4to. under the title of "Tentamen novæ Theoriæ Muſicæ ex certiſſimis harmoniæ principiis dilucidé expoſitæ, auctore Leonardo Eulero." This work, being written in Latin, and requiring in the reader, beſides that language, a knowledge in geometry, algebra, and fluxions, was little noticed by the public at large on its firſt appearance, and ſtill leſs underſtood by muſicians, for whoſe uſe it muſt have been chiefly intended. It, however, ſet mathematicians and men of ſcience to work, and ſtarted many curious ſubjects of meditation to ſuch as intereſted themſelves in the ſtudy of harmonics.

But we do not very well ſee how the author could with propriety call his treatiſe an attempt at a *new* theory of muſic. The ratios were all known ever ſince the time of Euclid. Indeed he has followed the proportions which Zarlino tried to eſtabliſh in his "Inſtitutioni," which had been adopted by Des Cartes, Rameau, Tartini, &c.; and Des Cartes, and others after him, had accounted for the pleaſure which we receive from concords, by the ſimplicity of the ratios between the ſounds which form them There is a plate, p. 35, repreſenting, we thought, in a new and ingenious manner to the eye, the pulſations of two ſtrings; the one fixed to a given tone, and the other tuned progreſſively to all the conſonant intervals, which clearly ſhews the coincidences of vibration, upon the frequency of which the degree of ſweetneſs and perfection in concords depends. We believe, however, that this was done in the 17th century, but in a leſs elegant manner, by our countryman lord keeper North, in a quarto pamphlet of only twenty-five pages, intitled, "A Philoſophical Eſſay of Muſick directed to a Friend;" London, 1677.

In this little tract the vibrations of each conſonance are repreſented to the eye, and the coincidences with the fixed tone, its baſe or principal, in the ſame manner as in the work of the great geometrician Euler, who has puſhed ratios as far as our perception and appreciation can go, extending the whole compaſs of our muſical ſyſtem to eight octaves. See COMPASS.

The degrees of ſuavity in conſonance from the ſimplicity of ratios and frequency of coincidence, had, we believe, been ſettled before the year 1739, when this treatiſe was publiſhed.

The following is a tranſlation of the titles of the ſeveral chapters of this work. After a preface of twenty pages,

Chap. I. treats of ſound, and the auditory ſenſe.
II. Of the ſweetneſs and principles of harmony.
III. Of muſic in general.
IV. Of concords.
V. Of concords in ſucceſſion.
VI. Of a ſeries of concords.
VII. Of intervals, and their names.
VIII. Of the genera of muſic.
IX. Of the diatonico-chromatico genus.
X. Of other more compounded genera.
XI. Of the concords in the diatonico-chromatico genus.
XII. Of the modes or keys and ſyſtems in the diatonico-chromatico genus.
XIII. Of the ratio of compoſition in a given mode and ſyſtem.
XIV. Of the modes and ſyſtems in tranſpoſed keys.

In the 13th chap. on the laws of compoſition, and the poſſible combinations in any given mode, key, or ſyſtem, ſome of theſe combinations employ every note in the ſcale, ſeemingly at once, which would be extremely offenſive if heard together. The author probably means, that all theſe ſounds may be heard ſucceſſively in melody, provided they are in tune, and have a fundamental baſe.

Upon the whole, Euler ſeems not to have invented much in this treatiſe; and to have done little more than arrange and methodize former diſcoveries in a ſcientific and geometric manner. He may, indeed, not have known what antecedent writers had diſcovered before; and though not the firſt, yet to have imagined himſelf an inventor.

EULER's *Logarithms*, or *Binary Logarithms*, are a ſpecies of artificial numbers contrived by M. Euler to facilitate the calculation and compariſon of muſical intervals, which they do, by repreſenting each interval in *decimal parts* of the octave, which is 1 in this notation, the ſucceſſive octaves or powers of 2 being repreſented by 2, 3, 4, &c. as in the following table, for the firſt 10 numbers, *viz.*

1 = 0.000000
2 = 1.000000
3 = 1.584963
4 = 2.000000
5 = 2.321928
6 = 2.584963
7 = 2.807356
8 = 3.000000
9 = 3.169925
10 = 3.321928

By help of the primes which compoſe muſical ratios, and their binary logarithms in this table, the Euler's logarithm may be found, which anſwers to any interval: as the names of the ſeveral intervals occur, we ſhall give their binary logarithms.

EULISIA, in *Ancient Geography*, a country of Scythia, towards the Palus Mæotis.

EULOGIUS, in *Biography*, patriarch of Alexandria, was, at firſt, preſbyter of the church of Antioch, and diſtinguiſhed himſelf by his zeal for the Catholic doctrines in a letter which he wrote to Eutychius, patriarch of Conſtantinople, containing an expoſition of the true faith. He was elevated to the ſee of Alexandria in the year 581, and became very active in rooting out hereſy, not only by the allowable and fair weapons of reaſon and argument, but by expelling from their ſituation all eccleſiaſtics who were advocates for the doctrine of one nature in Chriſt. He lived in habits of intimacy with Gregory the Great, whoſe ſentiments and diſpoſition were congenial to his own. He died in 608. Of his works only fragments are remaining. Moreri.

Eulogius, elected archbiſhop of Toledo in the ninth century, was born at Cordova about the year 800. He was educated for the prieſthood, and diſcharged the duties of that office with zeal and activity till the year 844, when he was driven into exile by the Saracens for his boldneſs in maintaining the principles of the Catholic faith. After much ſuffering he ventured to return to Cordova, where, in the year 850, he was thrown into priſon on account of his religion. In the dungeon he employed himſelf in writing animating exhortations to the Chriſtians, to ſupport and conſole them under their perſecution, for conſcience ſake, and to encourage them to undergo the ſevereſt trials rather than diſgrace themſelves by apoſtacy. He was afterwards liberated, and by his perſonal labours, as well as writings, perſevered in fortifying his fellow Catholics againſt the arts and terrors of their enemies. As a reward for his exertions in this hazardous employment, he was choſen to fill the vacant ſee of Toledo; but he was put to death before he could receive the epiſcopal conſecration. The accuſation againſt him was the having converted a young Mahometan female to the Chriſtian faith: he was beheaded in 859. He was author of "Memoriale Sanctorum, ſive Libri III. de Martyris Cordubenſibus;" "Apologeticus pro Martyribus, &c.;" "Exhortatio ad Martyrium;" and ſome moral epiſtles. Theſe were collected and printed with notes by Ambroſius Moralis in 1554, and again in a more correct form by Poncius Leo in 1574. Moreri.

EULOGY, Eulogia, in *Church Hiſtory*. When the Greeks have cut a loaf, or piece of bread, to conſecrate it, they break the reſt into little bits, and diſtribute it among the perſons who have not yet communicated, or ſend it to perſons that are abſent; and theſe pieces of bread are what they call eulogies.

The word is Greek, ευλογια, formed of ευ, *bene*, *well*, and λεγω, *dico*, *I ſay*, *ſpeak*; q. d. *benedictum*, *bleſſed*.

The Latin church has had ſomething like eulogies for a great many ages; and thence aroſe the uſe of their holy bread.

The name eulogy was likewiſe given to loaves or cakes brought to church by the faithful to have them bleſſed.

Laſtly, the uſe of the term paſſed hence to mere preſents made a perſon, without any benediction. See the Jeſuit Gretſer, in his Treatiſe de Benedictionibus & Maledictionibus, lib. ii. cap. 22. 24, &c. where he treats of eulogies thoroughly.

From a paſſage in Bollandus, on the Life of S. Melaine, cap. 4. it appears, that eulogies were not only of bread, but any kind of meat bleſſed and hallowed for that purpoſe. And that almoſt every body bleſſed and diſtributed eulogies; not only biſhops and prieſts, but even hermits, though laymen, made a practice of it. Women alſo would ſometimes ſend eulogies.

The wine ſent as a preſent was alſo held an eulogy. Bollandus remarks farther, that the euchariſt itſelf was alſo called eulogy.

Eulogy, likewiſe, means an encomium on any perſon, on account of ſome virtue or good quality.

EUMARIDES, of ευμαρης, *eaſy*, among the *Ancients*, a kind of ſhoes common to men and women.

The eumarides were uſed for pomp and delicacy, being neat, and painted with various colours.

EUME, in *Geography*, a river of Spain, which runs into the ſea near Corunna.

EUMECES, in the *Writings of the Ancient Naturaliſts*, the name of a ſtone which Pliny tells us reſembled a flint, and was found in Bactria; the ancients had an idle opinion, that, if laid under the head, it occaſioned true and prophetic dreams, foretelling to the perſon the more remarkable future events of his life. Hiſt. Nat. lib. xxxvii. cap. 10.

EUMENES, in *Biography*, a captain under Alexander the Great, was a native of Cardiopolis, in the Thracian Cherſoneſe. His father was of a low ſtation, but one in a condition to have entertained at his houſe Philip king of Macedon, who became the patron of his ſon. So well did the youth approve himſelf as ſecretary to the monarch, that his ſon Alexander continued him in the ſame office, and gave him a command in the cavalry. According to Plutarch, Eumenes took every advantage that his ſtation afforded him of accumulating money, for his tent being ſet on fire by the private orders of his ſovereign, to whom he had refuſed the loan of three hundred talents; there was found to the value of more than one thouſand talents in melted gold and ſilver. After the death of Alexander, when the provinces were divided among the principal commanders, the government of Cappadocia, Paphlagonia, and the country bordering on the Euxine ſea, as far as Trapezius, which as yet were unconquered, were aſſigned to Eumenes. Eumenes attached himſelf to Perdiccas, who made him his chief miniſter, and gave directions to Antigonus and Leonatus to put him in poſſeſſion of his government. Antigonus paid no attention to the order, but Leonatus, pretending to comply, marched an army ſeemingly for the purpoſe, which Eumenes joined. His deſign was, however, to ſeize the kingdom of Macedon for himſelf; but upon making it known, Eumenes deſerted him by night, after ſeizing his treaſures, and repaired to Perdiccas. In reward for his fidelity, Perdiccas himſelf made an expedition in Cappadocia, and after defeating and killing the king Ariathes, left Eumenes maſter of the country. He was next appointed prefect of Aſia, between mount Taurus and the Helleſpont, and was entruſted with the care of oppoſing the army expected to march againſt him out of Greece under Antipater and Craterus. On the approach of theſe great commanders, Eumenes concealed from his army that they were about to contend with Craterus, for whom they entertained the moſt profound reſpect and veneration, and giving battle to him and Neoptolemus, he ſlew the latter with his own hand, while Craterus was mortally wounded, fighting at the head of his phalanx. Eumenes, who felt for him emotions of the ſincereſt friendſhip, graſped his hand as he was expiring, wept over his remains, and honoured him with a magnificent funeral. After the murder of Perdiccas by his own army, Eumenes was declared a public enemy, and Antigonus was ſent to conduct the war againſt him. Eumenes was routed, but able to retire to the impregnable caſtle of Nora, which he defended with great ability. He was abundantly ſupplied with corn, and though without any other kind of proviſions, he kept his men in good humour, by his affable and cheerful demeanour. Another ſcene opened itſelf for the ambition of Antigonus, and Eumenes was ſet at liberty. He inſtantly began to levy troops, and in a ſhort time was declared royal general of Aſia, and there was aſſigned to him a guard of Argyraſpidæ, or ſilver ſhields. To inſpire his troops with a ſort of religious enthuſiaſm in the cauſe, he pretended to have ſeen Alexander in a viſion, by whoſe direction he erected a royal tent, containing a throne of gold, with all the enſigns of majeſty, where the captains were to offer incenſe, and then deliver their orders in a common council. After this there were diſputes about the chief command, but when Antigonus approached all agreed that Eumenes was the only general, under whom they would fight. His ſituation was difficult and precarious, he was aware that many of the other commanders were deſirous of getting rid of him, as the chief obſtruction to their ambitious deſigns. From thoſe whom he moſt ſuſpected he borrowed large ſums of money, that by ſuch a pledge he might give them an intereſt in his ſecurity. The war was protracted with various ſucceſs to a ſecond campaign, when a battle enſued, in which Eumenes routed the enemies' infantry, but in the mean time his cavalry took poſſeſſion of the camp of Eumenes. This circumſtance occaſioned ſo much diſcontent in the army, that when Antigonus ſent an offer to reſtore the ſoldiers, their wives and property, on condition of their delivering Eumenes into his hands, the Argyraſpidæ ſurrounded him, ſeized his ſword, tied his arms behind him, and gave him up priſoner. Antigonus being aſked how he ſhould be kept? As you would keep a lion or a wild elephant, he replied. All the Aſiatic chiefs ſubmitted upon this event, and it remained only to determine the fate of the illuſtrious captive. This was ſo long kept in ſuſpence, that Eumenes expreſſed his ſurpriſe that Antigonus had neither the courage to put him to death, nor the generoſity to make him his friend by ſetting him at liberty. A party in the army, headed by Demetrius, favoured the laſt meaſure, but the majority urged Antigonus to remove ſo formidable a rival. This counſel prevailed, and orders were given to deprive him of food. He had ſuffered the pains of hunger two or three days, and was faſt approaching his end, when the army being ſuddenly obliged to decamp, an executioner was ſent to diſpatch him. His remains were treated with funeral honours, and his aſhes were encloſed in a ſilver urn, and ſent to his family. This was in the year 315 B. C. Eumenes had a fine perſon, was highly accompliſhed, and poſſeſſed the manners and ſentiments ſuited to an elevated ſtation; he was faithful to the cauſe of his deceaſed maſter, and it was not till after his death that the captains who divided the Macedonian empire among them openly aſſumed the ſtyle of independent ſovereigns. Eumenes periſhed in his forty-fifth year. Univer. Hiſt. Plutarch.

Eumenes II. king of Pergamus, ſucceeded his father Attalus in the year B. C. 197. He cultivated the friendſhip of the Romans, who were now beginning to extend their influence into Aſia, urging them to check the ambitious projects of Antiochus the Great, of which he feared he ſhould be the victim. Eumenes joined his fleet to that of the Romans, and by his perſonal bravery greatly contributed to a naval victory, which was gained over that king; nor was he leſs uſeful at the deciſive battle of Magneſia. On account of his important ſervices he was rewarded by an acceſſion to his dominions, of all the countries weſt of mount Taurus, which had belonged to Antiochus, and alſo of all the provinces lying between that mountain and the river Meander, except Lycia and Caria, which were given to the people of Rhodes. Eumenes, now one of the moſt potent princes in Leſſer Aſia, was involved in a war with Pruſias, king of Bithynia, in which he was defeated both by land and ſea. Peace was made, and another conteſt took place between Eumenes and Pharnaces; in this the latter was obliged to ſue for peace. Eumenes now made an alliance with Antiochus, ſon of his old enemy Antiochus the Great, and in conjunction with his brother Attalus placed that prince on the throne of Syria, from which he had been driven by an uſurper. Perſes, king of Macedon, by increaſing his military force, excited the jealouſy of his neighbours, and Eumenes took a journey to Rome, for the purpoſe of acquainting the ſenate with all he had diſcovered of his dangerous projects. On his return, Eumenes, going to offer ſacriſice at the temple of Delphi, had nearly loſt his life by aſſaſſins hired by Perſes to deſtroy him. He received ſo much injury that he was carried almoſt lifeleſs on board his ſhip, and it was generally believed that he was actually dead. Attalus his brother, giving credit to the news, aſſumed the royal enſigns, and even married the queen Stratonice. Eumenes, after his recovery, gave his brother a friendly reception, adviſing him not to marry his wife again till it was certain he was dead. From this period he was engaged in conteſts with the Romans, who began to regard him with ſuſpicion, and it is thought they encouraged Attalus to ſeize upon his brother's kingdom for himſelf. Eumenes died in the year 159 B. C. leaving an infant ſon to the protection of his brother and ſucceſſor Attalus. Eumenes was liberal, and even magnificent towards his friends. He was a patron of letters, and made conſiderable additions to the celebrated library of Pergamus. Univer. Hiſt.

Eumenes, an orator, was an Athenian by deſcent, but was born at Autun in Gaul, where he was for a conſiderable time profeſſor of rhetoric, and acquired great reputation. He was ſecretary to the emperors Maximian and Conſtantius, and was much eſteemed by Conſtantine the Great, whom he harangued in favour of the inhabitants of Autun in 311. He delivered an oration before the prefect of Lyoneſe Gaul, in favour of the reſtoration of the public ſchools in the province, towards which he nobly offered to contribute his own ſalary, as ſecretary, probably, as well as profeſſor. He died about the middle of the fourth century. Fragments of his orations are printed in the "Panegyrici Veteres." Moreri.

EUMENIA, in *Ancient Geography*, a town of Aſia, in the Greater Phrygia, ſeated on the Cludrus.—Alſo, a town of Aſia Minor, in Caria.—Alſo, a town of Thrace, on the confines of Lower Mœſia.

EUMENIDEIA, *Ευμενιδεια*, an annual feſtival obſerved in honour of the Furies. It was otherwiſe called *σεμνων ἑορτη*, becauſe the Athenians called the Furies *σεμναι θεαι*, *i. e. venerable goddeſſes.*

EUMENIDES, in *Antiquity*. See Furies.

EUMETRES Beli, in *Natural Hiſtory*, the name given by the ancients to a gem which the Aſſyrians held ſacred to their god, and which many other nations learned from them to ſuppoſe very powerful againſt magic. Many have ſuppoſed this to be the one we now call oculus Beli: but this is an error, ſince Pliny, in his account of the eumetres, ſays, that it was of a very fine green. It was probably a gem of the emerald kind, that ſtone having ever been in very high eſteem in the Eaſtern part of the world, as it is alſo to this day.

EUMINACUM, in *Ancient Geography*, a town of

Mœſia, marked in the Itinerary of Antonine; 24 miles from Viminiacum,

EUMMÉ FAREGGÉ, or *Omm Faredje*, a canal of Egypt, joining lake Manzaleh with the Mediterranean; ſuppoſed to be the mouth of that ancient canal, called the Tanitic or Saitic branch of the Nile.

EUMOLPIDES, in *Antiquity*, prieſts of Ceres, who had the power among the Athenians of initiating into the myſteries of this goddeſs, or excluding from them.

EUMOLPUS, in *Biography*, a diſciple of Orpheus, who, tracing the footſteps of his father Muſæus, wrote concerning the myſteries of Ceres.

EUNAPIUS, a native of Sardis, in Lydia, flouriſhed in the fourth century, and was a kinſman of the celebrated ſophiſt Chryſanthius, at whoſe requeſt he wrote the lives of the philoſophers of his time. This work has been characterized by Brucker "as a maſs of extravagant tales, diſcovering a feeble underſtanding, and an imagination prone to ſuperſtition;" beſides being a ſophiſt, he was an hiſtorian, and practiſed phyſic. In his writings he ſeems to have entertained a great prejudice againſt Chriſtianity, the martyrs to which he treats with a contempt that has given juſt offence to contemporary eccleſiaſtical writers. He wrote a hiſtory of the Cæſars from Claudius II. to Arcadius and Honorius, of which only a fragment, "De Legationibus," is remaining. The "Vitæ Philoſophorum" was publiſhed with a Latin tranſlation by Junius in 1596. Moreri.

EUNILAK, in *Geography*, a place of Eaſt Greenland. N. lat. 61° 4′. W. long. 46°.

EUNOFIUS, a name given by ſome authors to the ætites, or eagle-ſtone.

EUNOMIANS, in *Eccleſiaſtical Hiſtory*, a ſect denominated from Eunomius, biſhop of Cyzicus, who, in the fourth century, maintained moſt of the errors of Arius, and added others to them. He was a native of Dacora, a town of Cappadocia, and removing to Conſtantinople, gained his ſubſiſtence firſt as a notary, and afterwards as a ſchoolmaſter. At Alexandria he became a diſciple of Aetius, whoſe opinions he adopted and ſtrenuouſly defended. Having been ordained a deacon by Eudoxius, biſhop of Antioch, he was deputed to the court of the emperor Conſtantius for the purpoſe of defending Eudoxius againſt the accuſations of Baſil, biſhop of Ancyra; but in his way thither he was ſeized by the partizans of Baſil, and baniſhed to Myda, a city in Phrygia. In the year 360 he was ordained biſhop of Cyzicus; but boldly avowing his opinions, he became obnoxious to the orthodox party, and underwent various and ſevere perſecutions. At the command of the emperor Conſtantius, he was at length condemned and depoſed by Eudoxius. At Chalcedon, whither he retired, his enemies purſued him, and he was afterwards baniſhed by the emperor Valens to Mauritania. At the cloſe of the reign of this emperor, after he had been allowed to return to Conſtantinople, he was charged with diſturbing the peace of the church, and again baniſhed to the iſland of Naxos. When Valens died, he returned to Chalcedon, but was ſoon ſent into exile by the emperor Theodoſius. Wearied by inceſſant and grievous perſecution he obtained leave from the court to retire to the place of his nativity, where he died at an advanced age, about the year 394. He was the author of various works, moſt of which are now loſt. Thoſe that are extant are "Eunomius's Creed," preſented to the emperor Theodoſius in the year 383, and his "Apologeticus," or Defence of his Doctrine, in which, according to Dr. Cave, the ſly arch-heretic reaſons ſhrewdly. Fabricius has publiſhed this piece entire, and an Engliſh verſion of it may be ſeen in the 1ſt volume of Whiſton's "Primitive Chriſtianity revived." Socrates Hiſt. Eccleſ. Cave's H. L. Fabr. Bib. Græc. vol. viii. Lardner.

EUNOMIŒUPSYCHIANS, a ſect of heretics of the fourth century, mentioned by Nicephorus, lib. xii. cap. 30. being the ſame with thoſe called Eutychians by Sozomen, lib. vii. cap. 17. See EUTYCHIANS.

EUNUCH, Ευνουχος, a term applied in the general to all who have not the faculty of generating, either through imbecility or frigidity; but more particularly to ſuch as have been caſtrated, or have loſt ſome of the parts neceſſary for that purpoſe.

The word is formed of ευνην εχει, q. d. *lecti curam habet*, *guardian*, or *keeper of the bed.*

In England, France, &c. eunuchs are never made but on occaſion of ſome diſeaſe which renders ſuch an operation neceſſary; but in Italy they make eunuchs for the ſake of preſerving the voice; and in the Eaſt they make eunuchs to be guards or attendants on their women.

Great numbers of children, from one to three years of age, are yearly caſtrated in Italy to ſupply the operas and theatres, not only of Italy but other parts of Europe, with ſingers; though it is not one in three, that, after having loſt their virility, have a good voice for a recompence. See CONSERVATORIOS.

Tavernier aſſures us, that in the kingdom of Boutan, in the Eaſt Indies, there are every year made twenty thouſand eunuchs, and ſold thence into other countries.

The ſeraglios of the Eaſtern emperors are chiefly ſerved and guarded by eunuchs; and yet we have very good teſtimonies, that the rich eunuchs in Perſia and other countries, keep ſeraglios for their own uſe. This is a puniſhment of crimes in ſome countries. See ADULTERY.

By an arret of the grand chamber of Paris in 1665, it is adjudged that an eunuch could not marry, not even with the conſent of the woman, and all the parties on both ſides.

Claudian has a very ſevere ſatire againſt the eunuch Eutropius, who had been elected conſul of Rome. He repreſents him as an old woman, dreſſed up in the honours of the conſulate.

In the council of Nice thoſe were condemned who, out of an indiſcreet zeal, and to guard themſelves from ſenſual pleaſures, ſhould make themſelves eunuchs. Such as thus mutilated their bodies were excluded from holy orders; witneſs Leontius, biſhop of Antioch, who was depoſed for having practiſed this cruelty on himſelf; and the biſhop of Alexandria excommunicated two monks who had followed his example, on pretence of ſecuring themſelves from the impetuous motions of concupiſcence.

Several of the emperors made very ſevere prohibitions againſt the making of eunuchs, or people's caſtrating themſelves. See CASTRATION.

EUNUCHS, *Eunuchi*, in *Eccleſiaſtical Hiſtory*, is alſo the denomination of a ſect of heretics in the third century, who had the folly or madneſs to caſtrate not only thoſe of their own perſuaſion, but even all they could lay hands on.

They took their riſe from the example of Origen, who, upon a miſunderſtanding of our Saviour's words in St. Matthew, chap. xix. ver. 12. made himſelf an eunuch, by cutting off the offending part, as ſome ſay; or as others (particularly St. Epiphanius), by the uſe of certain medicines. Theſe heretics were alſo called *Valeſians*.

EVOCATI, among the Romans, ſoldiers, who having ſerved their time in the army, went afterwards volunteers at the requeſt of ſome favourite general.

EVOCATION, EVOCATIO, among the Romans, a religious ceremony always obſerved by them at undertaking the ſiege of a town, wherein they ſolemnly called upon the gods and goddeſſes of the place to forſake it and come over to them. Without the performance of this ceremony, they either thought that the place could not be taken, or that it would be a ſacrilege to take the gods priſoners.

The form of evocation uſed at taking the city of Carthage is related by Macrobius, Sat. III. 9.

They always took it for granted that their prayer was heard, and that the gods had deſerted the place and came over to them, provided they were able to make themſelves maſters of it. The ancients had alſo two other ſorts of evocation; one was a magical operation, which they uſed in order to call up departed ſouls. This cuſtom of raiſing the manes, or conjuring up ſouls departed, was ſo ancient, that its origin is traced as high as the earlieſt periods of time; and all the anathemas denounced by the ſacred authors againſt thoſe who conſulted familiar ſpirits are proofs of the antiquity of this practice. Among the different ſorts of magic prohibited by Moſes, that of calling up the dead is expreſsly ſpecified. (See Witch *of Endor.*) Prophane authors look upon Orpheus as the inventor of this art, in evidence of which it is alleged, that the hymns which are aſcribed to him are moſtly real pieces of conjuration, but it is probable that this practice was derived from the people of the Eaſt, and was carried into Greece with other religious ceremonies, by colonies which came and ſettled here. It is certain, however, that in the time of Homer, this ſort of conjuration was practiſed, as it is mentioned in ſome paſſages of the Iliad. At that time it was not reckoned odious or criminal, ſince there were perſons who made public profeſſion of conjuring up ghoſts, and there were temples where the ceremony of conjuration was to be performed. Pauſanias (in Bœot.) ſpeaks of that which was in Theſprotia, where Orpheus came to call up the ſoul of his wife Eurydice. Ulyſſes's travels into the country of the Cimmerians, whither he went to conſult the ghoſt of Tireſias, deſcribed by Homer in the Odyſſey (l. xi.) ſeems to indicate a kind of conjuration. Hiſtorians, as well as poets, have mentioned this ſpecies of conjuration. Another ſort of evocation was that which was uſed in calling up the gods. In order to underſtand this practice, it ſhould be recollected, that it was a doctrine of the Pagan theology, that the gods preſided in a peculiar manner over certain places, and that ſeveral of theſe places were under the protection of the ſame god; and as it was impoſſible for him to be in them all at the ſame time, it was neceſſary to uſe the ceremony of evocation, when his preſence was thought needful. They had hymns proper to this operation, which they called κλητικοι, ſuch as were moſt of thoſe aſcribed to Orpheus, and thoſe of the poet Proclus. When they thought the patron god was arrived, they celebrated the feſtival named επιδημιαι. As ſoon as the danger, which made them invoke the gods was paſſed, they gave them liberty to go any where elſe; and they had other hymns for celebrating their departure, which hymns were called αποπεμπτικοι.

EVOCATORIÆ Epistolæ, among the Romans, letters ſent by the emperors to command the attendance of any perſon; or letters granting licence to any one to wait on the emperor; every perſon not being allowed this privilege till they had deſired and obtained the evocatoriæ epiſtolæ.

EUODIA, in *Botany*, from ευωδια, *a ſweet ſmell*, Forſt. Gen. 7. t. 7. See Fagara.

EVOLI, in *Geography*, a town of Naples, in Principato Citra; 15 miles E.S.E. of Salerno.

EVOLVENT, in *Geometry*, a term which ſome writers uſe for the curve reſulting from the evolution of a curve: in contradiſtinction to the evolute, which is the curve ſuppoſed to be opened or evolved.

The evolute always both touches and cuts the evolvent at the ſame time: the reaſon is, that it has two of its infinitely ſmall ſides in common with the evolvent; or, rather exactly placed on two equal ſides thereof; one of them within-ſide that of the evolvent, *i. e.* on the concave ſide thereof; and the other on the convex ſide of its correſpondent ſide; ſo that the evolute touches the evolvent in two points; whence, inſtead of being a tangent, it is ſaid to oſculate the evolvent; and, hence, it is alſo called *oſculator*, and *circulus oſculator*.

There is one, and but one oſculator, to each point of the evolvent; but to the ſame point there is an infinity of other circles which only touch, and do not oſculate. The oſculator, and the evolute, make no angle in the place where they touch and cut; nor can any curve line be drawn between, as there may between a tangent and a curve.

EVOLUTE, Evoluta, in the *Higher Geometry*, a curve firſt propoſed by Mr. Huygens, and ſince much ſtudied by the latter mathematicians. See Curvature.

The evolute is a curve, ſuppoſed to be evolved, or opened; and which, in opening, deſcribes other curves.

To conceive its origin and formation, ſuppoſe a flexible thread, wound exactly over the convexity of any curve, as A B C G (*Plate* VI. *Analyſis*, *fig.* 1.) and ſuppoſe the thread fixed in G, and every where elſe at liberty, to A. Now, beginning to unwind the thread from the point, and continuing it to D, and, throughout, keeping it tight on the curve ſurface A B C G, when the thread is become quite ſtraight, and is only a tangent, F G, to the curve in the point G, it is evident the extremity A, in its progreſs to F, has deſcribed another curve line A D E F.

Here, the firſt curve A B C G is called the evolute; each of its tangents B D, C E, &c. comprehended between it and the curve A D E F, called the *involute*, is called a *radius of the evolute*, or *radius oſculi*, *radius oſculator*, or radius of curvature, of the curve A D E F, in the reſpective points D, E, &c. And the circles, whereof the oſculators B D, C E, &c. are radii, are called *circuli oſculatores* of the curve A D E F, in D, E, &c. And, laſtly, the new curve reſulting from the evolution of the firſt curve begun in A, is called the *curve of evolution*, or *curve deſcribed by evolution*.

Evolute, *the radius of the*, then, is the part of the thread comprized between any point where it is a tangent to the evolute, and the correſpondent point where it terminates in the new curve. Which appellation, *radius*, is the more proper, as one may actually conſider this part of the thread in every ſtep it takes, as if it deſcribed an arc of an infinitely ſmall circle, making a part of the new curve, which thus conſiſts of an infinite number of ſuch arcs, all deſcribed from different centres, and with different radii.

Every curve, therefore, may be conceived as formed by the evolution of another. And we are to find that, whoſe evolution formed it; which amounts to the finding of the radius of the evolute in any point; for, as it is always a tangent to the generating curve, it is, properly, no more than one of its infinitely ſmall parts, or ſides, prolonged; and all its ſides, whoſe poſitions are determined of courſe, are no other than the generating curve itſelf.

The ſame thread is alſo called *radius curvedinis*, or *radius oſculi*, becauſe a circle deſcribed hereby, from the centre G, is ſaid to oſculate, or kiſs it, as both touching and cutting at the ſame time, *i. e.* touching both the inſide and the out.

Hence, 1. The evolute B C F (*fig.* 35.) is the place of all the centres of the circles that oſculate the curve A M, deſcribed by evolution. 2. When the point B fall on A, the radius of curvature, or radius of the evolute, M C, is equal to the arc B C; or to the aggregate of A B, and the arc B C. 3. Since the element of the arc M m, in the curve deſcribed by evolution, is an arc of a circle deſcribed by the radius C M; the radius of the evolute C M is perpendicular to the curve A M, or to a tangent at the point M. 4. Since the radius of the evolute M C is always a tangent to the evolute B C F, curves by evolution may be deſcribed through innumerable points, if only tangents be produced in the ſeveral points of the evolute, till they become equal to their correſpondent arcs.

The finding of the radii of evolutes is a thing of great importance in the higher ſpeculations of geometry; and even, ſometimes, is of uſe in practice as the inventor of the whole theory, Huygens, has ſhewn, in applying it to the pendulum. (Horol. Oſcill. part 3.) The doctrine of the oſcula of evolutes is owing to M. Leibnitz, who firſt ſhewed the uſe of evolutes in the meaſuring of curves.

We ſhall here ſubjoin a brief account of the method of finding the radius of the evolute in different kinds of curves and equations expreſſing the nature of evolutes.

1. To form a general expreſſion for (B E) the radius of the evolute, or of curvature at any point B in the involute curve A B Y, whoſe axis is A X, and evolute D E, *fig.* 3.

With the radius E B deſcribe the circular arc B K, which will have the ſame curvature with the involute curve A B at the point B. Draw the radius E K parallel to the axis A X, and produce the ordinate B C to L, to which draw A N parallel: let the abſciſs A C be $= x$, the ordinate C B $= y$, radius E B or E K $= r$, K N $= a$, and N A $= b$; then L E $= r - a - x$. If the abſciſs x be ſuppoſed to increaſe uniformly, and B m to be a tangent at the point B; and $m\,n$ be drawn parallel to B C, and B N parallel to A X; B n, $n\,m$, and m B, which are the contemporary increments of the abſciſs, ordinate, and curve, will be as their fluxions reſpectively; or B n will be as $\dot x$, $n\,m$ as $\dot y$, and B m $(= \overline{\mathrm{B}n^2 + n\,m^2}|^{\frac{1}{2}})$ as $\overline{\dot x^2 + \dot y^2}|^{\frac{1}{2}}$.

Farther, the triangles B $n\,m$ and B L E are ſimilar; therefore B $n : n\,m ::$ B L : L E, *i. e.* $\dot x : \dot y :: y + b : r - a - x$; conſequently, $r\dot x - a\dot x - x\dot x = y\dot y + b\dot y$: the fluxion of which equation (ſuppoſing $\dot x$ invariable, and therefore, the direction of the curve A B continually approaching towards a parallelism with its axis, the fluxion of $\dot y$ as negative) is $-\dot x^2 = \dot y^2 - y\ddot y - b\ddot y$; and $\dot x^2 + \dot y^2 = \overline{b + y} \times \ddot y$.

Again, L B : B E :: n B : B m, *i. e.* $b + y : r :: \dot x : \overline{\dot x^2 + \dot y^2}|^{\frac{1}{2}}$; therefore $b + y = \frac{r\dot x}{\overline{\dot x^2 + \dot y^2}|^{\frac{1}{2}}}$, and ſubſtituting this expreſſion for $b + y$, the above equation will become $\dot x^2 + \dot y^2 = \frac{r\dot x\ddot y}{\overline{\dot x^2 + \dot y^2}|^{\frac{1}{2}}}$; conſequently, $\overline{\dot x^2 + \dot y^2} \times \overline{\dot x^2 + \dot y^2}|^{\frac{1}{2}} = r\dot x\ddot y$, *i. e.* $\overline{\dot x^2 + \dot y^2}|^{\frac{3}{2}} = r\dot x\ddot y$, and $\frac{\overline{\dot x^2 + \dot y^2}|^{\frac{3}{2}}}{\dot x\ddot y} = r =$ B E. In deducing this expreſſion, the increment of the ordinate y, or the velocity or fluxion with which it flows, is ſuppoſed continually to decreaſe, therefore its ſecond fluxion is negative: but when y increaſes with an accelerated motion, its ſecond fluxion will be affirmative; and the above expreſſion will be $\frac{\overline{\dot x^2 + \dot y^2}|^{\frac{3}{2}}}{-\dot x\ddot y}$. By ſubſtituting 1 for $\dot x$, which is invariable in theſe expreſſions, they will become $\frac{\overline{1 + \dot y^2}|^{\frac{3}{2}}}{\ddot y}$ and $\frac{\overline{1 + \dot y^2}|^{\frac{3}{2}}}{-\ddot y}$ reſpectively; the former taking place when the curve is concave, and the latter when it is convex towards the axis, and the ſign of $\ddot y$ ſhewing the poſition of the evolute and radius of curvature with reſpect to the curve and axis. By reducing theſe expreſſions from the nature and properties of the curve, and always ſubſtituting 1 for $\dot x$, we ſhall obtain the value of B E, or the radius required. The vertical diſtance or radius A D may be eaſily obtained by ſubſtituting for $\dot x$, 1, and for $\dot y$ its proper value in the expreſſion for the ſubnormal C H, which is evidently $\frac{y\dot y}{\dot x}$. *E. gr.* 1. To find the radius of curvature at any point B in the parabola A Y, *fig.* 4.

Let the parameter be $= a$, abſciſs A C $= x$, and ordinate C B $= y$: then, by the nature of the curve $a\,x = y^2$, and therefore $a\dot x = 2y\dot y$ (ſee FLUXION), and making $\dot x = 1$, $a = 2y\dot y$, and $\dot y = \frac{a}{2y} = \frac{a}{2 \times \overline{a\,x}|^{\frac{1}{2}}}$. But the fluxion of this equation will be $-\ddot y = \frac{-a^2}{4 \times \overline{a\,x}|^{\frac{3}{2}}}$, or $\ddot y = \frac{a^2}{4 \times \overline{a\,x}|^{\frac{3}{2}}}$, and $\dot y^2$ being equal to $\frac{a^2}{4\,a\,x} = \frac{a}{4x}$, we ſhall have, by ſubſtituting theſe values in the expreſſion $\frac{\overline{1 + \dot y^2}|^{\frac{3}{2}}}{\ddot y}$ for $\dot y^2$ and $\ddot y$,

$$\frac{\overline{1 + \frac{a}{4x}}|^{\frac{3}{2}} \times \overline{4 \cdot a\,x}|^{\frac{3}{2}}}{a^2} = \frac{4}{a^2} \times \frac{\overline{4x + a}|^{\frac{3}{2}}}{4x} \times \overline{a\,x}|^{\frac{3}{2}} = \frac{4}{a^2} \times \overline{\frac{4\,a\,x^2 + a^2 x}{4x}}|^{\frac{3}{2}} = \frac{4}{a^2} \times \overline{\frac{1}{4}}|^{\frac{3}{2}} \times \overline{4\,a\,x + a^2}|^{\frac{3}{2}} = \frac{4}{a^2} \times \frac{1}{8} \times \overline{4\,a\,x + a^2}|^{\frac{3}{2}} = \frac{\overline{4\,a\,x + a^2}|^{\frac{3}{2}}}{2\,a^2}.$$

Then if a ſemicircle be deſcribed through the point B, C n be biſected in H, and H r be made equal 2 A C, and r E be a perpendicular at r, produced till it meets a line B E, drawn from B through H, this line B E will be the radius of curvature required: for B C^2 = A C × C n, 35 E. 3. or $\frac{\mathrm{B\,C}^2}{\mathrm{A\,C}} =$ C n, *i. e.* $\frac{a\,x}{x} = a =$ C n, and C H $= \frac{1}{2}\,a$, and C $r = \frac{1}{2}\,a + 2\,x$; and by 47 E. 1. $\overline{\mathrm{C\,H}^2 + \mathrm{C\,B}^2}|^{\frac{1}{2}} =$ B H, *i. e.* $\overline{\frac{1}{4}\,a^2 + a\,x}|^{\frac{1}{2}} =$ B H; and by 4 E. 6. C H : H B :: C r : B E; *i. e.* $\frac{1}{2}\,a : \overline{\frac{1}{4}\,a^2 + a\,x}|^{\frac{1}{2}} :: \frac{1}{2}\,a + 2\,x : \frac{a + 4x}{a} \times \overline{\frac{1}{4}a^2 + a\,x}|^{\frac{1}{2}} = \frac{\overline{a^2 + 4ax}|^{\frac{3}{2}}}{2\,a^2} =$ B E as before. A D the vertical diſtance, or, $\frac{y\dot y}{\dot x}$, is in this caſe, putting $\frac{a}{2y}$ for $\dot y$, and 1 for $\dot x$, equal to $\frac{a}{2}$; and this likewiſe appears, by conſidering, that in the expreſſion for the radius when the radius becomes equal to the vertical diſtance, the abſciſs x vaniſhes, and it becomes $\frac{\overline{a^2}|^{\frac{3}{2}}}{2\,a^2} = \frac{a^3}{2\,a^2} = \frac{a}{2}$.

E. gr. 2. To find the radius of curvature at any point B in the cycloid A B D, *fig.* 5.

Put the radius O F or O D $= a$, abſciſs A C $= x$, ordinate C B = y, ſine I G = s, and arc F G = z. Now by 35 E. 3. I G = $\overline{\mathrm{DI} \times \mathrm{IF}}|^{\frac{1}{2}}$, that is, $s = \overline{2ay - y^2}|^{\frac{1}{2}}$; the fluxion of which equation is $\dot{s} = \frac{a\dot{y} - y\dot{y}}{\overline{2ay - y^2}|^{\frac{1}{2}}}$; and by the nature of the cycloid, arc D G = G B; and therefore, arc F G = G I + A C, or A C = arc F G − G I, that is, $x = z - s =$ (by ſubſtituting for s its above value) $z - \overline{2ay - y^2}|^{\frac{1}{2}}$; and the fluxion of this equation, making $\dot{x} = 1$, is $1 = \dot{z} + \frac{y\dot{y} - a\dot{y}}{\overline{2ay - y^2}|^{\frac{1}{2}}}$.

But $\dot{z} = \overline{\dot{s}^2 + \dot{y}^2}|^{\frac{1}{2}}$ = (by writing for $\dot{s}$ its above value), $\overline{\frac{\overline{a\dot{y} - y\dot{y}}|^2}{2ay - y^2} + \dot{y}^2}|^{\frac{1}{2}} = \frac{a\dot{y}}{\overline{2ay - y^2}|^{\frac{1}{2}}}$; which, ſubſtituted for $\dot{z}$, makes the above equation $1 = \frac{a\dot{y}}{\overline{2ay - y^2}|^{\frac{1}{2}}} + \frac{y\dot{y} - a\dot{y}}{\overline{2ay - y^2}|^{\frac{1}{2}}}$; that is, $1 = \frac{y\dot{y}}{\overline{2ay - y^2}|^{\frac{1}{2}}}$; therefore, $\dot{y} = \frac{\overline{2ay - y^2}|^{\frac{1}{2}}}{y}$; and the fluxion of this equation (the fluxion of $\dot{y}$ being negative), is $-\ddot{y} = \frac{\frac{ay\dot{y} - y^2\dot{y}}{\overline{2ay - y^2}|^{\frac{1}{2}}} - \dot{y} \cdot \overline{2ay - y^2}|^{\frac{1}{2}}}{y^2} = \frac{-a\dot{y}}{y \cdot \overline{2ay - y^2}|^{\frac{1}{2}}} =$ (by writing for $\dot{y}$ its equal), $-\frac{a}{y^2}$; that is, $\ddot{y} = \frac{a}{y^2}$. Now, by ſubſtituting $\frac{2ay - y^2}{y^2}$ for $\dot{y}^2$, and $\frac{a}{y^2}$ for $\ddot{y}$, we have $\frac{\overline{1 + \dot{y}^2}|^{\frac{3}{2}}}{\ddot{y}} = \frac{\overline{1 + \frac{2ay - y^2}{y^2}}|^{\frac{3}{2}} \times y^2}{a} = \frac{\overline{2ay}|^{\frac{3}{2}}}{ay} = \frac{\overline{2ay \times 2ay}|^{\frac{1}{2}}}{ay} = 2 \cdot \overline{2ay}|^{\frac{1}{2}}$ = B E, the radius of curvature required.

Conſtruction.—Make F H = G B; and through the point H draw the right line B E, making B H = H E = chord F G; then will B E be the radius of curvature at the point B; for a tangent to the point B is parallel to the chord D G, and the radius of curvature is always perpendicular to the tangent; therefore, becauſe by 31 E. 3. the ∠ D G F is right, B E muſt be parallel to the chord F G. Now, by 4 and 8 E. 6. D F : F G :: G F : F I, or C B, ∴ G F = $\overline{\mathrm{DF} \times \mathrm{CB}}|^{\frac{1}{2}} = \overline{2ay}|^{\frac{1}{2}}$, and 2 G F = $2 \cdot \overline{2ay}|^{\frac{1}{2}}$ = B E.

2. To form a general expreſſion for the radius of curvature in ſpirals, or curves whoſe ordinates are referred to a fixed or central point:

Let C B Y, (*fig.* 6.) be the curve, C the central point, or that from which all the ordinates iſſue; and B E the radius of the curvature at the point B, that is, let the point E be ſuppoſed in the evolute curve: conceive C b and E b indefinitely near to C B and E B, that is, let the points B and b be ſuppoſed indefinitely near to each other; and let C F and C f be perpendicular to E B and E b reſpectively, then will the points F and r be indefinitely near to a coincidence; and therefore B r and C r may be taken as equal to B F and C F. Now, if with the ordinate C B as a radius, the little circular arc B n be deſcribed and conſidered as a little right line perpendicular to C b, and the increment B b be conſidered as coinciding with the tangent to the point B, then the little right-angled triangle B n b will be ſimilar to the right-angled triangle B F C; (for ∠ C B n = ∠ E B b; and therefore ∠ E B n being common, the ∠ C B F = ∠ n B b; and, conſequently, the angles at F and n being right, ∠ B C F = ∠ B b n); therefore by 4 E. 6. b B : B n :: C B : B F; that is, (if we put the ordinate C B = y, B n = x', and n b = y', when, by 47 E. 1 B b will be = $\overline{x'^2 + y'^2}|^{\frac{1}{2}}$,) $\overline{x'^2 + y'^2}|^{\frac{1}{2}} : x' :: y : \frac{x'y}{\overline{x'^2 + y'^2}|^{\frac{1}{2}}}$ = B F or B r; and B b : b n :: B C : C F, that is, $\overline{x'^2 + y'^2}|^{\frac{1}{2}} : y' :: y : \frac{yy'}{\overline{x'^2 + y'^2}|^{\frac{1}{2}}}$ = C F or C r; the increment of which is rf; that is, ſuppoſing x' to be invariable) $\frac{\overline{y'^2 + yy''} \times \overline{x'^2 + y'^2}|^{\frac{1}{2}} - \frac{y'y'' \times yy'}{\overline{x'^2 + y'^2}|^{\frac{1}{2}}}}{x'^2 + y'^2} = \frac{x'^2y'^2 + y'^4 + yx'^2y''}{\overline{x'^2 + y'^2}|^{\frac{3}{2}}} = rf$. Again, the triangles E B b and E r f being ſimilar, B b − rf : B b :: (B E − r E, or) r B : B E; that is, $(\overline{x'^2 + y'^2}|^{\frac{1}{2}} - \frac{x'^2y'^2 + y'^4 + yx'^2y''}{\overline{x'^2 + y'^2}|^{\frac{3}{2}}} =) \frac{x'^4 + x'^2y'^2 - yx'^2y''}{\overline{x'^2 + y'^2}|^{\frac{3}{2}}} : \overline{x'^2 + y'^2}|^{\frac{1}{2}} :: \frac{x'y}{\overline{x'^2 + y'^2}|^{\frac{1}{2}}} : \frac{y \times \overline{x'^2 + y'^2}|^{\frac{3}{2}}}{x'^3 + x'y'^2 - yx'y''}$ = B E, or B E = $\frac{y \times \overline{\dot{x}^2 + \dot{y}^2}|^3}{\dot{x}^3 + \dot{x}\dot{y}^2 - y\dot{x}\ddot{y}}$; which is a general expreſſion for the radius of curvature of all curves referred to a fixed or central point, when x' or $\dot{x}$ is invariable.

Hence, if $\dot{x}$ be made = 1, the general expreſſion for the radius of curvature will be = $\frac{\dot{y} \times \overline{1 + \dot{y}^2}|^{\frac{1}{2}}}{1 + \dot{y}^2 - y\ddot{y}}$. Wherefore, if we put the equation of the given ſpiral into fluxions, making $\dot{x} = 1$, and put this fluxional equation into fluxions again; and from thence, or from the nature of the curve, find the values of $\dot{y}^2$ and $\ddot{y}$: then, if for $\dot{y}^2$ and $\ddot{y}$ we ſubſtitute theſe their values in this general expreſſion, we ſhall have B E the radius of curvature required.

Otherwiſe. Let A R B be the propoſed curve, (*fig.* 7.) P the point, or centre, to which its ordinates are referred. N O L the evolute, and R O the ray of curvature at R. Moreover, let P H be perpendicular to R O; and ſuppoſing the ordinate P R (y) to become variable by the motion of the point R along the curve, let the fluxions of A R and P H (p), expreſſing the celerities of the points R and H in directions perpendicular to R O, be denoted by $\dot{z}$ and $\dot{p}$ reſpectively: the fluxions of quantities being always as the celerities by which the quantities themſelves increaſe in magnitude. (See FLUXION).

Therefore the celerities of any two points, in a right line revolving about a centre, being as the diſtances from that centre, it follows that $\dot{p} : \dot{z} ::$ O H : O R; whence by diviſion (putting R H = v) we have $\dot{z} - \dot{p} : \dot{z} :: v$ (R H) : R O = $\frac{v\dot{z}}{\dot{z} - \dot{p}} = \frac{vp\dot{z}}{p\dot{z} - p\dot{p}}$. But $p\dot{z} = y\dot{y}$.

and therefore R O $= \frac{v y \dot{y}}{y\dot{y} - p\dot{p}}$; which, becauſe $y^2 - p^2$ is $= v^2$ (and therefore $y\dot{y} - p\dot{p} = v\dot{v}$) will alſo be $= \frac{v y\dot{y}}{v\dot{v}} = \frac{y\dot{y}}{\dot{v}}$.

E. G. 1. Let the given curve A R (*fig.* 7.) be the logarithmic ſpiral, whoſe nature is ſuch, that the angle P R Q (or R P H) which the ordinate makes with the curve, is every where the ſame.

Then (denoting the ſine of that angle by b, and the radius of the tables by a) we have R H (v) $= \frac{by}{a}$, and therefore R O $\left(\frac{y\dot{y}}{\dot{v}}\right) = \frac{ay\dot{y}}{b\dot{y}} = \frac{ay}{b}$; which being to P R ($y$) in the conſtant ratio of a to b, or of P R to R H, the triangles R O P and R P H muſt therefore be ſimilar, and ſo the angle P O H, which the ordinate P O makes with the evolute, being every where equal to P R Q, will likewiſe be invariable. Whence it appears that the evolute is alſo a logarithmic ſpiral, ſimilar to the involute; and that a right line drawn from the centre, perpendicular to the ordinate of any logarithmic ſpiral, will paſs through the centre of curvature.

E. G. 2. To find the radius of curvature at any point B the ſpiral of Archimedes, C B, &c *fig.* 8.

Put the circumference of the generating circle A F, &c. $= a$, and its radius C A $= b$, ordinate C B $= y$, arc A F $= z$. Let C f be ſuppoſed indefinitely near to C F, that is, let the ∠ F C f be ſuppoſed indefinitely ſmall; and with the ordinate C B as a radius deſcribe the little circular arc B n, which put $= x'$; alſo put F $f = z'$. Now, by the nature of the curve, $a : b :: z : y$, or $z = \frac{ay}{b}$, the fluxion of which equation is $\dot{z} = \frac{a\dot{y}}{b}$; and by the ſimilar ſectors C B n and C F f, $y : x' :: b : z' = \frac{bx'}{y}$, or, $\dot{z} = \frac{b\dot{x}}{y}$. Hence, $\frac{a\dot{y}}{b} = \frac{b\dot{x}}{y}$; that is, (making $\dot{x} = 1$) $\frac{a\dot{y}}{b} = \frac{b}{y}$; from which equation we have $\dot{y} = \frac{b^2}{ay}$; therefore $\dot{y}^2 = \frac{b^4}{a^2y^2}$, and $\ddot{y} = \frac{-ab^2\dot{y}}{a^2y^2} =$ (by writing for $\dot{y}^2$ its value), $\frac{-b^4}{a^2y^3}$; and if we ſubſtitute for $\dot{y}^2$ and $\ddot{y}$ theſe their values, we ſhall have $\frac{y \times \overline{1+\dot{y}^2}|^{\frac{1}{2}}}{1+\dot{y}^2 - y\ddot{y}}$

$$= \frac{y \times \overline{1 + \frac{b^4}{a^2y^2}}|^{\frac{3}{2}}}{1 + \frac{b^2}{a^2y^2} + \frac{b^4}{a^2y^2}} = \frac{\overline{a^2y^2 + b^4}|^{\frac{3}{2}}}{a^2y^2 + 2ab^4} = \text{B E},$$

the radius of curvature ſought.

Conſtruction.—Through the centre C draw the indefinite right line H v perpendicular to the ordinate C B; draw the tangent T B, perpendicular to which draw B H; produce B C to V, making B R = T H and R V = C H; with B V and B R as radii, deſcribe the arcs V v and R r; draw the right line v B; and from the interſecting point r draw r E parallel to v H; then will B E be the radius of curvature at the point B: for, C T $= \frac{yz}{b}$, that is, by ſubſtituting $\frac{ay}{b}$ for z, C T $= \frac{ay^2}{b^2}$; and by 8 and 4 E. 6. T C : C B :: C B : C H, that is, $\frac{ay^2}{b^2} : y :: y : \frac{b^2}{a} =$ C H; therefore T H $=$ B R $=$ B $r = \frac{ay^2}{b^2} + \frac{b^2}{a}$, and B V $=$ B $v = \frac{ay^2}{b^2} + \frac{2b^2}{a}$; and by 47 E. 1. H B $= \overline{BC^2 + CH^2}|^{\frac{1}{2}} = \overline{y^2 + \frac{b^4}{a^2}}|^{\frac{1}{2}} = \frac{\overline{a^2y^2 + b^4}|^{\frac{1}{2}}}{a}$: again, by 4 E. 6. B v : B H :: B r : B E, that is, $\frac{ay^2}{b^2} + \frac{2b^2}{a} : \frac{\overline{a^2y^2+b^4}|^{\frac{1}{2}}}{a} :: \frac{ay^2}{b^2} + \frac{b^2}{a} : \frac{\overline{a^2y^2+b^4}|^{\frac{1}{2}}}{a} \times \frac{a^2y^2+b^4}{a^2y^2+2b^4} = \frac{\overline{a^2y^2+b^4}|^{\frac{3}{2}}}{a^3y^2+2ab^4} =$ B E.

3. To find an equation that ſhall expreſs the nature of the evolute of a given involute curve.

Let B E be the radius of evolution or curvature at any point B in the involute curve A B, *fig.* 9. whoſe abſciſs is A C $= x$, and ordinate C B $= y$. Parallel to H A draw E N; produce B C to L; and equal and parallel to C L, draw D N from the vertex of the evolute D E; then will the triangles B H C and B E L be ſimilar: and therefore, by 4 E. 6. B H : H C :: B E : E L, that is, $\frac{\ddot{y}}{\dot{x}} \times \overline{\dot{x}^2 + \dot{y}^2}|^{\frac{1}{2}} : \frac{y\dot{y}}{\dot{x}} :: \frac{\overline{\dot{x}^2+\dot{y}^2}|^{\frac{3}{2}}}{\dot{x}\ddot{y}} : \dot{y} \times \frac{\dot{x}^2+\dot{y}^2}{\dot{x}\ddot{y}} =$ E L; and H C : C B :: E L : L B, that is, $\frac{y\dot{y}}{\dot{x}} : y :: \dot{y} \times \frac{\dot{x}^2+\dot{y}^2}{\dot{x}\ddot{y}} : \frac{\dot{x}^2+\dot{y}^2}{\ddot{y}} =$ L B. Now, theſe are general expreſſions for E L and L B, when $\dot{x}$ is conſidered as invariable, and the fluxion of $\dot{y}$ as negative. Hence, therefore,

If $\dot{x} = 1$, and the fluxion of $\dot{y}$ be negative, the general expreſſion for B L will be $= \frac{1+\dot{y}^2}{\ddot{y}}$, and this multiplied by $\dot{y}$ is $\dot{y} \times \frac{1+\dot{y}^2}{\ddot{y}} =$ the general expreſſion for L E. Now, by help of the equation of the given involute curve, exterminate $\dot{y}$, $\dot{y}^2$, and $\ddot{y}$, out of theſe expreſſions, and find the vertical diſtance A D. Then, if we put the abſciſs of the evolute D N $= u$, and its ordinate N E $= v$; by help of theſe two equations, $u =$ B L $-$ B C, and $v =$ A C $-$ A D $+$ L E, we may get the nature of the evolute curve D E required.

Note.—If the given involute be convex towards its axis, and x and y increaſe together, or the fluxions of x and $\dot{y}$ be both affirmative, then the general expreſſions for B L and L E will be $\frac{1+\dot{y}^2}{-\ddot{y}}$; and $\dot{y} \times \frac{1+\dot{y}^2}{-\ddot{y}}$ reſpectively; wherein the negative ſign ſhews, that the points L and E muſt be taken on the concave ſide of the involute curve, that is, on the other ſide of it with regard to x and y.

E. gr. To find the nature of the curve A E P (*fig.* 10.) by whoſe evolution the cycloid A B D is deſcribed.

Put A C $= x$, C B $= y$, arc F G $= z$, and O D or O F $= a$; then by Ex. 2. art. 1. above, $\dot{y} = \frac{\overline{2ay - y^2}|^{\frac{1}{2}}}{y}$ $\dot{y}^2 = \frac{2ay - y^2}{y^2}$, and $\ddot{y} = \frac{a}{y^2}$; wherefore, B L =

1 +

$$\frac{\dot x^2 + \dot y^2}{\dot y} = \frac{\overline{1 + \frac{2ay - y^2}{y^2}} \times \dot y^2}{a} = 2y,$$ and L E $= \dot y \times$ B L $= \frac{\overline{2ay - y^2}|^{\frac{1}{2}}}{y} \times 2y = 2 . \overline{2ay - y^2}|^{\frac{1}{2}}$. Hence, if we put the abſciſs A N $= u$, and ordinate N E $= v$, we have u (= B L − C B =) $2y - y = y$, and $v =$ (A C + L E =) $x + 2 . \overline{2ay - y^2}|^{\frac{1}{2}}$ that is, (becauſe $x = z - \overline{2ay - y^2}|^{\frac{1}{2}}$) $v = z + \overline{2ay - y^2}|^{\frac{1}{2}}$, or, (writing u for y its equal,) $v = z + \overline{2au - u^2}|^{\frac{1}{2}}$. Wherefore, the evolute curve A E P is a cycloid, and equal to the given cycloid A B D; for, let A S = S V = a, then (A N being = F I,) A T = F G = z, and N T $= \overline{2au - u^2}|^{\frac{1}{2}}$ = I G; and therefore, A T + T N $= z + \overline{2au - u^2}|^{\frac{1}{2}}$, that is, A T + T N = N E, which is the property of the cycloid; therefore, the evolute A E P is a cycloid; and becauſe A V = F D, therefore the cycloids A E P and A B D are equal. See Cycloid.

The evolute of a ſpiral, or indeed of any other curve, may be deſcribed by finding the radii of curvature at ſeveral points in the involute; for then we ſhall have as many points in the evolute, through which if a curve line be drawn, it will be the evolute ſought.

Wolf. Elem. Math. tom. i. p. 524, ſeq. or the Infinim. Petites of M. le Marquis de l'Hopital. Simpſon's Fluxions, vol. i. p. 71, &c. And Rowe's Fluxions, edit. 3. 1767, chap. vi. and vii. p. 103—132.

Since the radius of an evolute is either equal to an arc of an evolute, or exceeds it by ſome given quantity, all the arcs of evolutes may be rectified geometrically, whoſe radii may be exhibited by geometrical conſtructions; whence we ſee why an arc of a cycloid is double its chord; the radius of the evolute being double the ſame, and the evolute of a cycloid being itſelf a cycloid, equal and ſimilar to the involute.

M. Varignon has applied the doctrine of the radius of the evolute to that of central forces; ſo that having the radius of the evolute of any curve, one may find the value of the central force of a body; which, moving in that curve, is found in the ſame point where that radius terminates; or reciprocally, having the central force given, the radius of evolute may be determined. Hiſt. de l'Acad. Roy. des Sciences, an. 1706.

The variation of curvature of the line deſcribed by the evolution of a curve, is meaſured by the ratio of the radius of curvature of the evolute, to the radius of curvature of the line deſcribed by the evolution. See Maclaurin's Flux. art. 402. prop. 36.

Evolute, *imperfect.* M. Reaumur has given a new kind of evolute, under this denomination. Hitherto the mathematicians had only conſidered the perpendiculars let fall on the points of the convex ſide of the curve; if other lines not perpendicular were drawn upon the ſame points, provided they were all drawn under the ſame angle, the effect would be the ſame; that is, the oblique lines would all interſect within the curve; and by their interſections, form the infinitely ſmall ſide of a new curve, whereof they would be ſo many tangents.

This curve would be a ſort of evolute, and would have its radii; but an imperfect evolute, ſince the radii are not perpendicular to the firſt curve. Hiſt. de l'Acad. &c. an. 1709.

EVOLUTION, in *Geometry*, the unfolding or opening of a curve, and making it deſcribe an evolvent.

The word *evolutio* is formed of the prepoſition *e, out*, and *volvo, I roll*, or *wind*; q. d. an *unwinding*, or *unrolling.*

The equable evolution of the periphery of a circle, or other curve, is ſuch a gradual approach of the circumference to rectitude, as that its parts do all concur, and equally evolve, or unbend; ſo that the ſame line becomes ſucceſſively a leſs arc of a reciprocally greater circle, till at laſt they change into a ſtraight line. In the Philoſophical Tranſactions, N° 260, a new quadratrix to the circle is found by this means, being the curve deſcribed by the equable evolution of its periphery.

Evolution, in *Algebra*, is alſo uſed for the extraction of roots out of powers. In which ſenſe it ſtands oppoſed to involution. See Extraction *of roots.*

Evolution, as relating to *Military* operations, muſt be underſtood to be founded on the principles of Tactics (which ſee), and be conſidered indiſpenſably neceſſary to the ſafety, the progreſs, and the ſucceſs of all bodies of men, whether large or ſmall. The term is generally uſed as ſynonymous with manœuvre, but in ſtrictneſs they are by no means to be ſo accounted; for an evolution rather relates to an open, candid, and undiſguiſed movement, made either for a change of poſition, or for the general purpoſes of attack and defence; while a manœuvre applies abſtractedly to deceptious movements, to feints, and to that kind of trick which gives riſe to the ſaying ſo common among us, "I have out-manœuvred him." Thus the French, from whom we have directly borrowed the term, ſay, "un ruſé manœuvre," *i. e.* a cunning fellow; and among them a ſkilful ſeaman is deſignated "un manœuvrier."

In every ſervice, both in the military and naval departments, certain regulations exiſt which direct, that all candidates for promotion ſhould be acquainted, not ſimply with the ſeveral motions of the firelock, and the ordinary duties of individuals, but with a variety of movements to be made by entire battalions, or armies, and by either ſingle ſhips, ſquadrons, diviſions, or fleets reſpectively. It being our intention to amplify under the head of Tactics, *military* and *naval*, we ſhall in this place confine ourſelves to thoſe evolutions which, forming a part of the Britiſh diſcipline, ought to be thoroughly underſtood by every perſon whoſe purſuits tend towards the goal of martial celebrity; and ſhould be thoroughly underſtood by every officer, of whatever rank.

The following nineteen changes will be ſufficient for the purpoſe, under the remark, that we pre-ſuppoſe a battalion to be arranged at cloſe order, and all in readineſs for performing the required evolutions.

Evolution 1.

On a rear diviſion.	Form cloſe column of companies behind grenadiers. Form cloſe column of two companies. Face and march to the right. Deploy on the rear diviſion.	*Explanation.*—The column marches *quick*, 20 or 30 paces to the right, and, without halting, begins to deploy into line on the rear diviſion. The commanding officer of the battalion gives the word, for each diviſion to halt, front.

Evolution 2.

On a front diviſion.	Form cloſe column of companies in front of the left. Form cloſe column of two companies. Face and march to the left. Deploy on the front diviſion.	The column marches *quick*, 30 or 40 paces to the left, and, without halting, begins to deploy on the front diviſion. The commanding officer of the battalion gives the word for each diviſion to halt, front.

Evolution 3.

On a central diviſion.	Form cloſe column of companies on a central company, either flank in front, and facing to the rear. Countermarch of each diviſion in cloſe column. Deploy on any central named company.	The cloſe column is formed facing to the rear. It then countermarches each diviſion, ſo as to return to the proper front. In the central deployment by companies, the company officers give the words reſpectively to halt, front.

Evolution 4.

Change of poſition in open column.	Wheel back into open column of companies, the right in front. March forward 30 or 40 paces. Enter an oblique line (the three or four leading companies), by wheeling ſucceſſively to the left, a half-wheel. Halt. The rear companies file into column. Wheel up into line.	The battalion, thus, at an intermediate point, enters an alignment, on which it is to form.

Evolution 5.

Wing thrown back.	The left company is wheeled back till parallel with the original poſition. The reſt of the companies wheel into echellon. March to the rear. Form on the left company.	The whole companies wheel back at the ſame time; the left company twice the number of paces that the others do. Should it be neceſſary for the ſubſequent movements, the line may retire 50 or 60 paces, and then front.

Evolution 6.

Countermarch, and change of poſition.	Wheel back into open column, the right in front. Countermarch companies by files. March in column 30 or 40 paces. Head diviſion halts cloſe to the head of column. Form ſquare, and prepare for firing. Re-form in cloſe column. Open out to open column from the rear, and halt. Change head of column, by the countermarch of companies, from the rear to the front. Column moves on and halts. Wheel up into line.	After the countermarch by files, the column ſtands with its left in front. The column cloſes in quick time. The ſquare is formed, and cloſe column re-formed. The column opens out in quick time from its rear diviſion, and halts. The countermarch by companies, from the rear to the front, is in ordinary time. When the line is formed, it is then conſiderably to the reviewing general's right, and with its rear to him.

Evolution 7.

Countermarch by files on the centre of the battalion.	This brings back the battalion to its original front.

Evolution 8.

March in open column.	Form open column behind the left company, which is put in march when the third company has taken its place in column. The right ſub-diviſions double. The column halts, and pivots are corrected. Wheel up into line.	The companies that are filing incline towards the head of the column; ſucceſſively front at their wheeling diſtances, aſcertained as uſual by their ſerjeants; take up the ordinary ſtep, and follow in open column. When the column is marching ſteadily, the whole ſub-diviſions double at once, at one command, and again move up at another.

Evolution 9.

Echellon change of poſition.	Wheel back into open column, the left in front. The third company is wheeled back, the 8th of a circle, and each of the others 3-16ths of the circle. Form line on the third company by the echellon-march.	The line is thus formed oblique, from open column, on a central company, by the echellon-march.

Evolution 10.

Change of poſition.	The left company is wheeled up the 8th of a circle, and each of the others 1-16th. Form line by the echellon-march.	The line thus changes poſition to the front, on the left company, by the echellon-march.

Evolution 11.

Change of poſition.	The battalion faces to the right. March in file 50 or 60 paces. Halts. Wheels up into line, except the light company, which files quickly to the right, and forms behind the colours.	The column of companies is formed by the rear men of each moving up quickly to the left of their leaders, and of each other: the officers move to pivot flanks, and pivots are inſtantly corrected. The column halts when the colours are oppoſite to the general.

Evolution 12.

Retreat in line.	The battalion retires (50 paces). Halts; fronts. Fire twice by companies from centre to flanks. Retire by alternate companies in two lines (250 paces, each retreat about 50 paces.) Form line. Retire in line (50 paces). Halt; front.	The light company, being previouſly ſubdivided and prepared, acts in the retreat by alternate companies, filling up, or at leaſt occupying the intervals in the firſt line, and retiring with it to the ſecond, in which it continues to ſet in like manner, and thus alternately. When the line halts, and fronts, it reſumes its place on the left.

Evolution 13.

March to flank in echellon.	Companies make a half wheel to the right. March in echellon, (250 paces.) Wheel back on the march into parallel line. Forward (100 paces.) Halt. Fire thrice by companies, from flanks to centre.	At the word "wheel back into line," the pivot flanks mark time, and the divisions wheel back in ordinary time. At the proper inſtant, when the battalion is formed, the commander gives the word "Forward," for the whole to advance by the colours, and to correct any irregularity there may be in the battalion.

[Hitherto the battalion may have been *two* deep, but if its companies can muſter ten files each, the corps may now be formed *three* deep.]

Evolution 14.

Movements in the ſquare.	Form ſquare. March the ſquare by the left. Angle of the front face (50 paces.) Halt; form ſquare. March ſquare by the left face. Halt; form ſquare. March ſquare by the rear face. Halt; form ſquare. Fire in ſquare by companies. Form the line.	The ſquare is formed by the echellon march of companies. After the march by the left face, the ſquare is formed when oppoſite the general. The line is formed by the echellon wheel-up, and march of companies. When the order is given to form line, the light company marches quickly, and places itſelf two deep, and in two diviſions, ten or twelve paces behind the two centre companies.

Evolution 15.

Retiring, and filing to the rear.	Retire in line (100 paces.) File by companies from the proper right. Halt in open column, the right in front. Wheel up into line.	When the line has paſſed the light company twenty paces, that company extends to cover the centre of the battalion, and follows at 50 or 60 paces diſtance; and when the column halts to form, the light company paſſes quickly through and beyond it. The companies file quickly to the rear. The battalion forms line at the extremity of its ground; the light company 30 paces in its rear.

Evolution 16.

Filing, advancing, and charging to the front.	Advance in line (50 paces.) File from the right of companies to the front (50 paces.) Halt in open column, the left in front. Wheel up into line. Advance in line (50 paces.) Advance by alternate half battalions, and fire four times.	Before the line advances, the light company quickly forms, extended 30 paces before the centre, and preſerves that diſtance in advancing. When the column halts to form, the light company paſſes quickly to the rear, and aſſembles half of it behind each flank, then moves relatively with the flank-companies, till after the charge of bayonets. The alternate half-battalions fire, the two firſt ranks ſtanding.

Evolution 17.

Charge and purſuit.	Form line. Advance (50 paces.) Fire volley. Advance (50 paces.) Fire volley. Charge bayonets (50 paces.) Halt. Load.	After the volley, bayonets are ported; the battalion advances firm by the centre at the quick ſtep, and at the word "Halt," the front rank comes down to the charging poſition. The word "Prime and Load" is then given, and the light company, iſſuing from behind the flanks, purſue, return, and aſſemble, and join on the left of the battalion.

Evolution 18.

Retiring in line.	Retire in line (100 paces.) Retire by alternate half battalions. Fire four times. Retire in line (100 paces, or more.) Halt. Front.	The whole battalion being aſſembled, the alternate half-battalions fire, the two front ranks ſtanding.

Evolution 19.

Advance in line and ſalute.	Advance in line (100 paces.) Halt. Fire two vollies. Port arms at the laſt one, and half cock. Open ranks. Advance within 50 paces of reviewing general. Halt. General ſalute.	In the vollies the front rank kneels. The muſic may occaſionally play, and the drums roll, as the line advances. The muſic will play while advancing at open ranks.

We have ſelected this portion of the diſcipline ordered for the Britiſh army, becauſe it comprizes ſufficient changes to give our readers a correct idea of what are termed *evolutions*. Theſe are ſo contrived as to be performed on a very moderate extent of ground; each evolution ſerving to correct any obliquity, or lateral change of poſition, and confining the regiment within certain limits.

It may be proper to remark, that though the foregoing relate in this inſtance to a ſingle regiment under review, the whole of the charges may be conſidered as repreſenting thoſe made by a large army; the ſeveral companies being the repreſentatives of regiments, or of larger bodies. See BATTALION.

Fa. Hoſte, a Jeſuit, in 1697, printed a Treatiſe on Naval Evolutions, in folio. By naval evolutions he means the motions made by a fleet, ſquadron, or naval armament, in order to put themſelves in a proper diſpoſition for attacking the enemy, or defending themſelves with the moſt advantage. See TACTICS.

EVOLVULUS, in *Botany*, from *evolvo, to roll out or unfold*, in oppoſition to *Convolvulus*, with which the preſent genus agrees in habit, except in not having a convoluted ſtem. Linn. Gen. 152. Schreb. 204. Willd. Sp. Pl. v. 1. 1516. Juſſ. 134. Claſs and order, *Pentandria Tetragynia*. Nat. Ord. *Campanaceæ*, Linn. *Convolvuli*, Juſſ.

Gen. Ch. *Cal.* Perianth inferior, of five lanceolate, acute, permanent ſegments. *Cor.* of one petal, regular, wheel-ſhaped, plaited, ſlightly five-cleft. *Stam.* Filaments five, capillary, ſpreading, almoſt as long as the corolla; anthers rather oblong. *Piſt.* Germen ſuperior, nearly globular; ſtyles four, capillary, ſpreading, the length of the ſtamens; ſtigmas ſimple. *Peric.* Capſule nearly globular, of four cells and four valves. *Seeds* ſolitary, roundiſh, angular on the inner ſide.

Eſſ. Ch. Calyx of five leaves. Corolla five-cleft, wheel-ſhaped. Capſule ſuperior, of four cells. Seeds ſolitary.

Willdenow has ſeven ſpecies, five of which were known to Linnæus. Among the latter is *E. linifolius*, Linn. Sp. Pl. 392. (Convolvulus linifolius; Am. Acad. v. 4. 306. Syſt. Nat. ed. 10. v. 2. 923. Brown. Jam. t. 10. f. 2.) whence he informs us he derived the above generic character, having the plant alive under his own inſpection. It is a ſmall inconſpicuous annual, with ſlender, ſtraight, ſpreading ſtems; narrow, lanceolate, hairy leaves; and little, blue, axillary flowers; native of low ground in Jamaica.

The other ſpecies have rounder leaves, but otherwiſe agree very much with the above. They grow in the Eaſt or Weſt Indies, and are annuals of humble growth, and no conſpicuous attractions, being inferior in beauty to the meaneſt ſpecies of *Convolvulus*.

E. *tridendatus*, Linn. Sp. Pl. 392, is now returned to *Convolvulus*, ſee that genus, ſp. 19.

EUONYMUS, ευωνυμον of Theophraſtus, ſo called by antiphraſis, from ευωνυμος, *having a good name*, becauſe the plant was *infamous* for its ſtrong fœtid ſmell, and its poiſonous quality to cattle. Spindle-tree. Linn. Gen. 107. Schreb. 148. Willd. Sp. Pl. v. 1. 1130. Juſſ. 377. Gærtn. t. 113. Claſs and order, *Pentandria Monogynia.* Nat. Ord. *Dumoſæ*, Linn. *Rhamni*, Juſſ.

Gen. Ch. *Cal.* Perianth inferior, flat, in four or five deep, equal, roundiſh, concave ſegments. *Cor.* Petals four or five, ovate-oblong, flat, ſpreading, longer than the calyx. *Stam.* Filaments four or five, awl-ſhaped, erect, ſhorter than the petals, inſerted, alternately with them, into a glandular receptacle; anthers two-lobed. *Piſt.* Germen ſuperior, pointed; ſtyle ſhort, ſimple; ſtigma obtuſe. *Peric. Capſule* ſucculent, coloured, depreſſed, with four or five angles, and as many cells and valves. *Seeds* ſolitary, ovate, each wrapped up in a pulpy arillus.

Eſſ. Ch. Calyx flat. Petals five. Capſule ſuperior, five-ſided, coloured, of five cells and five valves. Seeds in a pulpy covering.

A genus of extra-tropical ſhrubs, the produce of Europe, North America and Japan. Willdenow has ſeven ſpecies. They are deſtitute of hairineſs, and have oppoſite branches and leaves; the latter ſimple, deciduous, more or leſs elliptical, entire or toothed, with ſcarcely any ſtipulas. Flowers of a dull or greeniſh hue, in axillary forked panicles, not ornamental. Fruit much more conſpicuous and often very beautiful, on account of the pink, waxy hue of the capſule, varying occaſionally to white, and orange coverings of the ſeeds.

E. Tobira. Thunb. Jap. 99. (Tobira; Kæmpf. Am. Exot. 796, cum ic.), a native of Japan, has terminal flowers, and in many other reſpects ſeems not perfectly to accord with this genus.

E. europæus. Sm. Fl. Brit. 262. Engl. Bot. t. 362; and *E. verrucoſus*, Jacq. Auſtr. t. 49; alſo *E. latifolius*, Jacq. Auſtr. t. 289; are good examples of it. Linnæus confounded them together as varieties, but Scopoli, and afterwards Jacquin, have well diſtinguiſhed them. The laſt ſpecies in particular is very remarkable for its warty branches, ſlender habit, reddiſh flowers, and ſmall pale capſules, out of which the black ſeeds, partially clothed with their ſcarlet arillus, hang by ſlender threads. The wood of all of them is tough, and uſed for ſkewers and ſpindles. It ſhould be cut in the ſummer. The fruit ſerves in many places to decorate churches and ruſtic kitchens at Chriſtmas-time. It is reported to be dangerouſly emetic and purgative.

Euonymus, in *Gardening*, comprehends plants of the hardy flowering ſhrubby kind, of which the ſpecies cultivated are, the common ſpindle-tree (*E. europæus*); the warted ſpindle-tree (*E. verrucoſus*); the purple-flowered ſpindle-tree (*E. atropurpureus*); the ever-green ſpindle-tree (*E. americanus*); and the broad-leaved ſpindle-tree (*E. latifolius.*)

The evergreen ſort of ſpindle tree has a variety with variegated leaves.

Method of Culture.—All the four more common ſorts may be propagated either by ſeeds, layers, or cuttings of the young ſhoots; but the evergreen kind requires a different method.

In the firſt mode, the ſeeds ſhould be ſown in the clumps or borders in the early autumn, covering them well in. In the following autumn the plants ſhould be removed, and ſet out in nurſery rows, being kept well cleared from weeds during the ſummer. After two or three years growth in this ſituation, they will be fit to plant out for good, in proper ſituations.

With reſpect to the young ſhoots, they may be laid down in the autumn, a ſlit being made at the joint placed the deepeſt in the ground. In the following autumn they will be well rooted, and may be taken off and planted out in the manner of the ſeedling plants.

The cuttings ſhould be made eight or ten inches in length, and planted in a ſhady border in the autumn. When they have ſtruck full root, they ſhould be carefully removed, and managed as thoſe raiſed from the ſeed.

But the two laſt methods, and thoſe of budding and grafting, are the only ones by which the green variety can be continued with certainty and ſucceſs.

With regard to the laſt ſpecies, it is beſt increaſed by laying down the young branches after being tongued in the autumn, managing them afterwards in the ſame manner as the others.

Theſe plants are ſufficiently hardy to bear the open air, when planted in warm ſheltered ſituations.

They are all very ornamental plants; the four common ſorts producing a fine effect by their berry-like ſeeds, and the laſt ſort but one by its evergreen leaves; the chief objection to the former kinds being their great aptitude to have their leaves compleatly eaten up by the caterpillars ſoon after they are fully expanded.

EVORA, or Elvora, anciently *Ebora*, in *Geography*, an ancient, walled and fortified, large but not populous, city of Portugal, the capital of the province of Alentejo, and an archbiſhop's ſee, ſituated on a gentle eminence in a fruitful plain, ſurrounded by hills, near the centre of the province; 65 miles E. Liſbon. The ſtreets are narrow, crooked, and full of angles. It has no trade or manufactures; but contains five pariſh churches, twenty-three religious houſes, and about twelve thouſand inhabitants. The cathedral and other buildings are high and in the Gothic ſtyle. This city is ſaid to have been founded by the Phœnicians, and walled round by Sertorius, who ſupplied the town with water by means of a beautiful aqueduct, (ſince entirely rebuilt by John III.,) and who, after having reſided there for a conſiderable time, was buried, as tradition reports, in this place. Julius Cæſar conſtituted it a municipium, and named it Liberalitas Julia. It was taken by the Moors in the year 715, and retaken by the Chriſtians under Giraldo, whoſe heroic conduct is celebrated by Camoens in his Luſiad, in 1166, and then reduced under the dominion of Alphonſo Henriques. In 1540 it was erected into an archiepiſcopal ſee by pope Paul III.; and the firſt prelate founded an univerſity, now fallen into decay. In this city are the remains of a temple of Diana, 7 pillars of which are ſtanding, of the Corinthian order, connected by a plaſter-wall. This edifice, at firſt a pagan place of worſhip, was converted into a Mooriſh moſque, and is now the butchers ſhambles. There are many other Roman veſtiges, inſcriptions, &c. particularly in the great ſquare, which indicate the antiquity of this place. Its fortifications are 12 baſtions, and two demi-baſtions, and a caſtle in ruins. On the north ſide of Evora the hills riſe, being round the town adorned with gardens, and on their ſummits with evergreen oaks. The road from hence to Montemor o novo, which lies at the diſtance of five leagues, paſſes over granite hills, partly covered with corn fields, and partly with fine woody or evergreen oaks and paſtures. N. lat. 38° 30′. W. long. 7° 42′.

EVORAMONTE, a town of Portugal, in the province of Alentejo, ſeated on a rock, and containing about 800 inhabitants; 15 miles N.E. of Evora. N. lat. 38° 42′. W. long. 7° 31′.

EVORIA, a town of European Turkey in Livadia; 24 miles N. of Lepanto.

EUOSMA, in *Botany*, from ευοσμος, *ſweet-ſmelling*, becauſe the flowers have the ſcent of hawthorn-bloſſoms. Jackſon in Andr. Repoſ. t. 520. Claſs and Order, *Pentandria Monogynia*. Nat. Ord. *Rotaceæ*, Linn. *Gentianæ*, Juſſ.

Gen. Ch. *Cal.* Perianth inferior, in five deep, obovate, concave, equal, permanent ſegments. *Cor.* of one petal, bell-ſhaped; tube dilated, as long as the calyx, pervious; limb in five broad, ſhort, obtuſe, ſpreading lobes. *Stam.* Filaments five, awl-ſhaped, ſhorter than the tube, inſerted into its lower part, alternate with the lobes of the limb; anthers incumbent, roundiſh, compreſſed. *Piſt.* Germen ſuperior, oval, two lobed; ſtyle very ſhort and thick; ſtigma capitate, four-lobed, on a level with the anthers. *Peric.* Capſule ovate, pointed, with a longitudinal furrow on each ſide, ſwelling irregularly from the projection of the ſeeds, of two valves, whoſe inflexed edges divide it into two cells; receptacles one in each cell, linear, triangular, parallel to the valves and cloſe to the partitions. *Seeds* five or ſix in each cell, in two rows, oval, flattened on the inner ſide, all over rough with minute tubercles.

Eſſ. Ch. Calyx deeply five-cleft. Corolla bell-ſhaped, with a five-cleft border. Stigma four-lobed. Capſule ſuperior, with two furrows and two cells, burſting at the top. *Seeds* ſeveral, oval, rough, affixed to a triangular receptacle.

1. *E. albiflora.* Andr. Repoſ. t. 520. Native of New South Wales, in the country near Port Jackſon, from whence ſpecimens and ſeeds were long ago ſent by Dr. White. It is ſaid to bear our winters in the open ground, flowering in April. *Stem* ſhrubby, with numerous, oppoſite, ſlender, ſquare, leafy, ſlightly downy branches. *Leaves* oppoſite, on ſhort ſtalks, lanceolate, acute, entire, ſmooth; ſhining and deep green above; paler, opaque, and ſomewhat glaucous beneath. *Stipulas* ſmall, briſtle-ſhaped, in pairs at the baſe of each footſtalk, ſomewhat hairy. *Flowers* in denſe, axillary, bracteated panicles, much ſhorter than the leaves; ſnow-white, ſmall, but copious, and very fragrant. *Capſules* about a quarter of an inch long, obtuſe, rugged, tipped with the ſhort permanent ſtyle.

The characters above given will, we believe, diſtinguiſh this genus from *Exacum*, to which it is moſt allied of any in the ſame natural order. See Exacum.

EVOVÆ, a barbarous word, ſays Rouſſeau, formed of the ſix vowels, which begin the ſyllables of the words *ſeculorum amen*, and which is only uſed in canto fermo. It is from the letters of this word that the tone is found in the pſalms and antiphonaria of the Roman catholic church, and the notes by which the verſes of the pſalms and canticles muſt be terminated.

The evovæ always begins by the dominant of the mode and ends upon the final.

EVOUTS, in *Geography*, a ſmall iſland in the Southern Pacific ocean; 15 miles S. from Terra del Fuego. S. lat. 55° 33′. W. long. 67° 36′.

EUPAREA, in *Botany*, ευπαρεια, *having beautiful cheeks*, in alluſion probably to the ſcarlet colour of the flowers, ſaid to reſemble *Anagallis arvenſis*. Gærtn. v. 1. 230. t. 50. Schreb. 156. Willd. Sp. Pl. v. 1. 1183. Mart. Mill. Dict. v. 2. Claſs and order, *Pentandria Monogynia*. Nat. Ord. *Lyſimachiæ*, Juſſ.

Gen. Ch. *Cal.* Perianth inferior, of five lanceolate, acute leaves. *Cor.* Petals from five to twelve, lanceolate, ſpreading, longer than the calyx. *Stam.* Filaments five; anthers. *Piſt.* Germen roundiſh, ſuperior; ſtyle briſtle-ſhaped, long; ſtigma ſimple. *Peric.* Berry dry, globoſe, crowned with the permanent ſtyle, of one cell. *Seeds* numerous, roundiſh, ſmall, affixed to a globoſe, fungous, central receptacle.

Eſſ. Ch. Calyx of five leaves. Petals from five to twelve. Berry ſuperior, dry, of one cell, with many ſeeds. Receptacle globoſe.

E. *amœna* is the only known ſpecies, gathered in New Holland by ſir Joſeph Banks and Dr. Solander. Gærtner deſcribes it as a procumbent plant, reſembling *Lyſimachia nummularia*, but about one-fourth its ſize. Flowers of the colour of the Scarlet Pimpernel. He adds that "the ſeed-veſſel, which-ever way preſſed, would not open by regular valves, ſo that it is very nearly allied to *Trientalis*." Indeed his figures betray the very cloſe affinity, even the identity of theſe two genera, except that one is deſcribed as polypetalous, the other monopetalous, and that the ſtamens of *Euparea* are not ſaid to equal the petals in number, when the latter are more than five.

EUPATORIA, formerly Koslof, or *Goſleve*, in *Geography*, a town and diſtrict of Ruſſia, in the province of Taurida or Crim Tartary, near the Black ſea. N. lat. 45° 40′. E. long. 33° 14′.

Eupatoria, or *Pompeiopolis*, in *Ancient Geography*, *Akmeſchid*, a town in the N.W. part of the Tauris Cherſoneſus.

Eupatoria, *Amid*, a town of the kingdom of Pontus, ſituated in the gulf of Amiſa, and contiguous to a town of the ſame name. Mithridates Eupator is ſaid to have built it, and to have given it his name.

EUPATORIUM, in *Botany*, ευπατωριον of Dioſcorides, from Mithridates, ſurnamed Eupator, who is reported to have brought this plant into uſe as a counter-poiſon. Linn. Gen. 413. Schreb. 546. Willd. Sp. Pl. v. 3. 1748. Sm. Fl. Brit. 859. Mart. Mill. Dict. v. 2. Juſſ. 178. Gærtn. t. 166. Claſs and order, *Syngeneſia Polygamia-æqualis*. Nat. Ord. *Compoſitæ diſcoideæ*, Linn. *Corymbiferæ*, Juſſ.

Gen. Ch. *Common Calyx* oblong, imbricated; ſcales linear-lanceolate, erect, unequal, unarmed. *Cor.* compound, uniform, diſcoid; florets all uniform, perfect, fertile, monopetalous, funnel-ſhaped, with a regular, five cleft, ſpreading border. *Stam.* Filaments five, capillary, very ſhort; anthers united into a cylindrical tube. *Piſt.* Germen minute; ſtyle thread-ſhaped, very long, cloven down as far as the top of the anthers, ſtraight; ſtigmas ſlender, bluntiſh, ſtraight. *Peric.* none, except the permanent calyx. *Seeds* ſolitary, oblong, angular; down long, rough, or feathery. *Recept.* naked.

Eſſ. Ch. Receptacle naked. Down rough or feathery. Calyx imbricated, oblong. Style prominent, cloven half way down, divaricated.

A large genus, chiefly, though not entirely, American. The *roots* are perennial. *Stem* ſometimes ſhrubby. *Leaves* oppoſite, moſtly ſimple, and ſtrongly ſerrated. *Flowers* corymboſe, terminal, numerous, white, blueiſh, or reddiſh. Whole plant, roughiſh, bitter, or aromatic. Willdenow has 71 ſpecies.

E. *cannabinum*, Engl. Bot. t. 428, ſingular for having fingered leaves, which indeed are ſometimes found undivided, is the only Britiſh ſpecies. It grows in watery places about the banks of rivers, or in mountainous boggy thickets, where it with us ſupplies the place of the Swiſs *Cacalia alpina*, which its pink flowers ſomewhat reſemble.

Several of the American ſpecies are eſteemed in that country, on account of their aromatic and tonic qualities, and known by the name of Fever root, or Fever weed. Among theſe, we believe, are E. *ſeſſilifolium*, *perfoliatum*, and *aromaticum*, but we want further information on this ſubject.

E. *Aya-pana*, Venten. Jard. de la Malmaiſon, t. 3, a native of the banks of the river of the Amazons, is ſaid to be "an excellent ſudorific and alexipharmic;" partaking therefore, no doubt, of the virtues of the above-mentioned ſpecies. Its *leaves* are lanceolate, nearly entire, and not accurately oppoſite. The *flowers* are purpliſh.

E. *zeylanicum*, Linn. Sp. Pl. 1172, has decidedly alternate leaves, ſo as to have raiſed a doubt in the mind of Linnæus whether it could belong to this genus; yet its fructification ſeems altogether like the generality of the ſpecies.

EUPEGIUM, in *Ancient Geography*, a town of Greece, in the Peloponneſus.

EUPEN, or Oepen, in *Geography*, a town of France, in the department of the Ourthe, and chief place of a canton in the diſtrict of Malmedy; 4 miles E.N.E. of Limburg. The place contains 6,749, and the canton 12,616 inhabitants, on a territorial extent of 102½ kiliometres and ſeven communes. Here is a conſiderable manufacture of cloth.

EUPETALOS, in *Natural Hiſtory*, the name of a gem deſcribed by the ancients as famous for its variety of colours. Pliny, lib. xxxii. cap. 10. tells us, that it ſhewed at once blue, fire-colour, red-lead colour, and yellow. It ſeems to have been the opal, and that Pliny's deſcription of it in this place was taken from ſome author he did not perfectly underſtand, as is the caſe in many of his accounts from the Greeks.

EUPHASEE, in *Geography*, the ancient name of Hiwaſſee river in Teneſſee, N. America; alſo the name of an Indian town on its S.W. bank, 28 miles from its mouth. See Hiwassee.

EUPHEMISMUS, Ευφημισμος, of ευ, *well*, and φημι, *I ſpeak*, in *Rhetoric*, a figure which expreſſes things in themſelves diſagreeable and ſhocking, by terms implying the contrary quality; that is, the Pontus, or Black ſea, having the epithet of αξενος, (i. e. *inhoſpitable*) given it on account of the ſavage cruelty of thoſe who inhabited the neighbouring countries; this name, by euphemiſm, was changed into that of Euxinus. Thus Ovid. Triſt. lib. iii. eleg. 13.

> "Dum me terrarum pars pene noviſſima Ponti
> Euxinus falſo nomine dictus habet."

In which ſenſe it only makes a ſpecies of irony. But every euphemiſm is not irony; for we ſometimes uſe improper and ſoft terms in the ſame ſenſe with the proper and harſh. See Voſſ. Rhet. lib. iv. cap. 186, ſeq.

EUPHEMIUS, in *Biography*, ſucceeded to the high dignity of patriarch of Conſtantinople in the year 490. He was zealouſly attached to the doctrines of the Catholic church, of which he gave proof by ſtriking out from the liſts of perſons in communion with the church, the name of Peter Mongus, patriarch of Alexandria, becauſe that prelate had pronounced an anathema againſt the council of Chalcedon. This circumſtance produced a violent ſchiſm between the two patriarchs, who convened their reſpective ſynods, in which they mutually procured excommunications of each other to be iſſued. In the year 491, on the death of Zeno, when Anaſtaſius was taking meaſures to ſecure the imperial throne, Euphemius warmly oppoſed him, on account of his known Arian principles, and when he found his oppoſition fruitleſs, he refuſed to crown the new emperor till he had delivered to him a written confeſſion of orthodox faith, and engaged under his hand, and by the ſanctity of an oath, to maintain the principles of the Catholic doctrine, as eſtabliſhed by the council of Chalcedon. In the year 493, Theodoric, having become maſter of Italy, ſent ambaſſadors to Anaſtaſius to treat for peace, to which Euphemius was thought to be the chief obſtacle. In a ſhort time afterwards Anaſtaſius having confidentially informed the patriarch of his deſire to terminate in an honourable manner the war in which he was engaged with the Iſaurians, Euphemius betrayed his ſecret to the patrician John, the father-in-law of Athenodorus, one of the chiefs of the Iſaurians. The emperor was made acquainted with the patriarch's conduct, and laid the caſe before an aſſembly of biſhops, who were convened at Conſtantinople in the year 495, and by his influence with them, obtained a decree that Euphemius ſhould be depoſed, and cut off from the communion of the church. He afterwards obtained a ſentence of baniſhment againſt Euphemius, who died at Ancyra in the year 515. Moreri.

EUPHON, in *Acouſtics*, a muſical inſtrument lately contrived by Dr. Chladni of Wittemberg, who, in conſequence of a variety of experiments on the longitudinal vibrations of elaſtic bodies, conſtructed this inſtrument, ſo called from its pleaſant ſound, which conſiſts of glaſs tubes diſpoſed in a proper frame, and expreſſing their ſounds by being rubbed longitudinally. The euphon has ſome reſemblance to a ſmall writing deſk. When opened, the glaſs tubes, of the thickneſs of the barrel of a quill, and about 16 inches long, are ſeen in an horizontal poſition. They are wetted with water by a ſponge, and ſtroked with the wet fingers in the direction of their length, ſo that the increaſe of the tone depends merely on the ſtronger or weaker preſſure, and the ſlower or quicker movement of the fingers. The number of tubes is 42. In the back part there is a perpendicular ſounding-board divided in the middle, through which the tubes paſs. From this conſtruction it appears, that the euphon ſhould not be conſidered as an altered or improved harmonica, (See Armonica), but as a totally new and different inſtrument. In regard to ſweetneſs of ſound, it approaches very near to the harmonica; but it poſſeſſes ſeveral advantages, peculiar to itſelf. It is ſimpler, with regard both to its conſtruction and the movement neceſſary for producing the ſound, as neither tuning nor ſtamping is required, but merely the movement of the finger. It produces its ſound more ſpeedily; ſo that as ſoon as it is touched you may have the tone as full as the inſtrument is capable of rendering it; whereas in the harmonica, the tones, particularly the lower ones, muſt be made to increaſe gradually.

It has alſo greater diſtinctneſs in quick paſſages, becauſe the tones do not reſound ſo long as in the harmonica, where the ſound of one low tone is often heard when you wiſh only to hear the following tone. The uniſon is purer than is generally the caſe in the harmonica, where it is difficult to have perfect glaſſes, which in every part give like tones with mathematical exactneſs. It is however as difficult to be tuned as the harmonica. It does not affect the nerves of the performer; for a perſon ſcarcely feels a weak agitation in the fingers; whereas in the harmonica, particularly in concords of the lower notes, the agitation extends to the arms and even through the whole body of the performer. This inſtrument is leſs expenſive than the harmonica; when one of the tubes breaks, or any other part is deranged, it can ſoon be repaired, and at very little expence: whereas, when one of the glaſſes of the harmonica breaks, it requires much time and is very difficult to procure another capable of giving the ſame tone as the former, and which will correſpond ſufficiently with the ſeries of the reſt. For an account of the experiments that led the author to the conſtruction of this inſtrument, and of the various ſtages of his progreſs in the improvement of it, we refer to the Philoſophical Magazine, vol. ii. p. 391, &c.

EUPHONIC Accent. See Accent.

EUPHONY, in *Elocution* and *Compoſition*, that ſweet or pleaſing quality in the ſucceſſive ſounds of language, which reſults from happy combinations of the enunciative elements, ſuch eſpecially as, though eſſentially different in their characteriſtic powers, melt eaſily into each other ſo as to preſerve an uninterrupted flow of utterance through the reſpective members of a ſentence, without labour to the ſpeaker, or offence to the hearer. The word is formed of ευ, *bene, well*, and φωνη, *vox, voice*. Quintilian calls *euphonia, vocalitas*; Scaliger, *facilis pronunciatio*. The moſt obvious rule with reſpect to euphonic compoſition is that a due mixture ſhould be made of conſonants and vowels; and the principle of this rule may be at once explained and illuſtrated by the following parody on a famous but ſophiſtical couplet in Pope's Eſſay on Criticiſm,

"Your conſonants with vowels well combine,
And twelve ſmall words may flow in one ſmooth line."

But this is not all that is requiſite for perfect euphony: every vowel does not blend with equal grace and facility with every conſonant; nor is every ſucceſſion of mere vowels, or every ſucceſſion of conſonants, equally offenſive or cacophonous. Words or ſyllables, for example, terminating with thin vowels, may be followed by other words or ſyllables, commencing with broad or open vowels, or the reverſe, with very happy effect; and ſome conſonants may be brought together, in immediate ſucceſſion, even as terminative and initial elements of following ſyllables or words, in ſuch way as rather (while they increaſe the ſonorous energy of ſuch compoſition,) to diverſify the time and expreſſion, than to diſturb the euphony of the ſentence. All the liquids eſpecially (thoſe that properly ought to be, as well as thoſe that commonly are ſo called) combine with almoſt equal facility with other liquids, and with vowels or with the conſonants, whether ſemi-liquids, ſibilants, or mutes. (See Liquid, Mute, &c.) Which of theſe, and under what circumſtances, may be thus brought together, with the happieſt effect of euphony and expreſſion, it would require a much longer diſcuſſion than we have ſpace for, to aſcertain; and, after all, much muſt be left to the taſte, the ear, and the experimental diſcrimination of the writer. But it is not upon the writer alone, that the effect of euphony depends. The reader or reciter muſt alſo do his part, for though it is very poſſible ſo to write, that no organs, and no management of thoſe organs, can elicit in the delivery, any thing but the diſſonance of cacophony; there are ſome pedants who contrive to render even the ſmootheſt compoſitions harſh and cacophonous, and then aſcribe to their native language, (of the very elements and genius of whoſe oral compoſition they are utterly ignorant,) the diſguſting diſſonance which does, in reality, belong to their own jargonized utterance. Euphony in the reader or ſpeaker depends principally upon his ſkill and management in the articulation and implication of the ſucceſſive elements, ſyllables, and words as explained under the term Enunciation; and upon his giving full tune, and ſufficient quantity to the liquids and liquifiable conſonants. Cacophony (the antagoniſt of Euphony) on the contrary, reſults in the reader, from the laboured ſeparation of terminatives and initials, that might eaſily have been implicated; from giving unneceſſary impulſe and force to the mutes, from hurrying over the liquids, and partially tuneable elements, as if they were mere mutes, and from perpetual unneceſſary interruptions in the ſtream of enunciative delivery.

EUPHORBIA, in *Botany*, ευφορβιον of Dioſcorides, ſo named after Euphorbus, phyſician to Juba king of Lybia. Spurge. Linn. Gen. 243. Schreb. 326. Willd. Sp. Pl. v. 2. 881. Sm. Fl. Brit. 513. Mart. Mill. Dict. v. 2. Juſſ. 385. Claſs and order, *Dodecandria Trigynia*. Nat. Ord. *Tricoccæ*, Linn. *Euphorbiæ*, Juſſ.

Gen. Ch. *Cal.* Perianth inferior, of one leaf, inflated, ſomewhat coloured, with four, in ſome few inſtances five, marginal teeth, permanent. *Cor.* Petals, or Nectaries, four, ſometimes five, turbinate, gibbous, thick, abrupt, unequal in ſituation, alternate with the teeth of the calyx, inſerted into its margin by their claws, permanent, bearing plenty of honey. *Stam.* Filaments numerous, 12 or more, threadſhaped, jointed, longer than the corolla, inſerted into the receptacle, coming to maturity at different periods, ſeparated by briſtly ſcales; anthers roundiſh, of two diſtinct lobes. *Piſt.* Germen ſuperior, roundiſh, three-ſided, elevated on a ſtalk above the margin of the calyx; ſtyles three, cloven; ſtigmas obtuſe. *Peric.* Capſule ſtalked, roundiſh, three-lobed, of three cells, and three valves which ſeparate elaſtically. *Seeds* ſolitary, roundiſh.

Obſ. The petals or nectaries are for the moſt part four, in ſome flowers five, which often happens on the ſame plant, ſuch flowers being furniſhed with ſtamens only, without a piſtil, and coming forth earlier than the reſt. In many the petals are glandular, in others creſcent-ſhaped, or toothed; in ſome few thin and membranous; they are commonly ſituated as it were on the outſide of the calyx. The capſule is either ſmooth, or hairy, or warty.

Eſſ. Ch. Calyx of one leaf, inflated, inferior. Nectaries four or five, inſerted into the calyx. Capſule ſtalked, three-lobed.

A vaſt, but very natural, genus, whoſe ſpecies amount in Willdenow's work to 124. They are divided into ſeveral ſections. All abound with an acrid milk.

Thoſe of the firſt ſection have a very peculiar thick, ſhrubby, fleſhy, angular ſtem, armed with ſpines, and bearing few or no leaves. To this belongs *E. officinarum*, probably the original ſpecies. See its figure in Commelin's Hort. Amſt. v. 1. t. 11. Alſo *E. antiquorum*, ib. t. 12, an Eaſt Indian plant, which ſeems very improperly named, as neither agreeing with the deſcriptions of the ancients, nor growing in the country whence they procured their ευφορβιον.

The ſecond ſection has ſhrubby ſtems without thorns, neither forked nor umbelliferous. As *E. Caput Meduſæ*, Comm. Hort. t. 17, common in Green-houſes; and *E. petiolaris*, Curt. Mag. t. 883.

The third has forked ſtems, not umbelliferous, and the plants are moſtly herbaceous and annual, as *E. picta*, Jacq. Ic. Rar. t. 477, and *pilulifera*, t. 478; alſo *E. Peplis*, Engl. Bot. t. 2002, common on the ſea ſhores of the ſouth of Europe.

The fourth has the flowers in an umbel, three-branched in the firſt inſtance, and the branches ſubſequently forked repeatedly, each ſubdiviſion of the infloreſcence accompanied by a pair of heart-ſhaped, unequal ſided, ſomewhat coloured bracteas, as our common weed *E. Peplus*, Curt. Lond. faſc. 1. t. 35. Engl. Bot. t. 959.

The fifth has a four-branched umbel, as the great *E. Lathyris* of the gardens, commonly called the Caper tree, remarkable for its long, dark, four-rowed leaves. There are but few ſpecies in this ſection.

The ſixth, a numerous ſection, has a five-branched umbel, like the common *E. helioſcopia*, Curt. Lond. faſc. 1. t. 36. Engl. Bot. t. 883; and the rare and ſplendid *E. punicea*, Sm. Ic. Pict. t. 3, a ſhrubby Jamaica plant, of which a moſt miſerable ſpecimen is drawn in Jacq. Ic. Rar. t. 484.

The ſeventh and laſt ſection conſiſts of ſuch ſpecies as have numerous rays to the common umbel, like *E. Cypariſſias*, Engl. Bot. t. 840, frequent in gardens, and *amygdaloides*, t. 256, very common in woods.

Euphorbia, in *Gardening*, comprehends plants of the herbaceous, ſhrubby, ſucculent kinds, the principal cultivated ſpecies of which are; the triangular ſpurge (E. antiquorum); the Canary ſpurge (E. canarienſis); the officinal ſpurge (E. officinarum); the Meduſa's head ſpurge (E. caput Meduſæ); the myrtle-leaved ſpurge (E. tithymaloides); the ſeven-angled ſpurge (E. heptagona); the warty-angled ſpurge (E. mammilaris); and the Cape ſpurge (E. lathyris): the firſt ſpecies is a large plant, of which there is a variety with a naked three-cornered compreſſed ſtalk, ſending out a great number of erect branches, which are likewiſe generally three-cornered, but ſometimes four-cornered; armed with ſhort crooked ſpines, having no leaves. The plants have not, we believe, yet produced flowers in this climate. This variety, like the ſpecies from which it is produced, is a native of the Eaſt Indies.

The fourth ſpecies has alſo a variety frequently denominated the "Little Meduſa's head," which has a thick ſhort ſtalk, ſeldom more than eight or ten inches in height, from which come out a great number of ſlender trailing branches, about a foot in length, intermixing, and having the ſame appearance with the other, but ſmaller and much ſhorter; the ends are beſet with narrow leaves, between which the white flowers come out and appear. Its native ſituation is the ſame as that of the ſpecies from which it is derived. According to ſome there are likewiſe a double branching, a dwarf trailing, and other varieties.

The fifth ſort has alſo laurel leaved and variegated leaved varieties.

Method of Culture.—Theſe different ſorts of plants may be raiſed by planting cuttings, which have been made at a joint, five or ſix inches in length, after having been rolled in ſand, and laid upon a ſhelf for ſome days to have the wounds healed over, in the ſummer ſeaſon about the middle, chooſing ſmall pots for the purpoſe filled with light, dry, ſandy mould, with ſome rubbiſh at the bottoms, ſuch as that formed of one fourth part of lime-rubbiſh which has been well ſcreened, the ſame quantity of ſea ſand, and one half of the whole of light freſh vegetable earth, which ſhould be very well mixed and incorporated together, by being often turned over; then plunging the pots in the bark hot bed, giving due ſhade when the weather is hot and ſunny, with a little water occaſionally once or twice a week. As ſoon as the plants have ſtricken root, air ſhould be admitted to them pretty freely in the ſituation in which they may be; or they may, in order to be hardened, be removed into the ſtove.

In the after management they ſhould be allowed larger pots annually as they advance in growth, and be often refreſhed with water during the ſummer months, but very ſparingly in the winter ſeaſon.

It may be remarked that moſt of theſe ſorts of plants are capable of being kept in the hot-houſe, on the ſhelves, and ſome of them, as the fifth, ſixth, and ſeventh ſorts, in a dry airy green-houſe, or glaſs caſe, during the winter months, great care being taken to protect them well from the froſts; being ſet out in the ſummer in the open air: but the fourth ſpecies requires ſome ſort of ſupport in order to prevent the branches, by their weight, forcing it upon the pots; as by this ſort of treatment the plants will riſe to the height of four or five feet, throwing out a great number of ſide branches. The eighth kind, however, requires little or no particular care after it has been once introduced, except merely that of keeping the young plants clean, as it will be continued by its ſcattering the ſeeds.

All theſe plants, with the exception of the laſt, afford great variety in collections of the hot and green-houſe kinds; and that alſo in the clumps and borders of the pleaſure grounds, among others of the leſs hardy ſorts.

EUPHORBIÆ, in *Botany*, the 96th natural order in Juſſieu's ſyſtem, or the 1ſt of his 15th claſs. The definition of this claſs is,—Cotyledons two. Petals none. Stamens in a ſeparate flower from the piſtils. Its characters are thus more fully explained. Flowers either monoecious, that is, males and females together on the ſame plant, or dioecious, on ſeparate ones; very rarely hermaphrodite. Calyx in all of one leaf, or a ſcale ſupplying its place. Corolla none, except occaſionally ſome ſcales, or internal diviſions of the calyx, reſembling petals. In the male flowers the ſtamens are inſerted either into the upper or lower part of the calyx, or ſcale which ſupplies its place, definite, or rarely indefinite, in number; their filaments diſtinct, or rarely united into a central ſtalk, originating from the middle of the calyx. Germen in the females ſimple, or ſometimes more than one, ſuperior, or rarely inferior; ſtyle one, or ſeveral, rarely wanting; ſtigma either ſolitary or more than one. Fruit either ſuperior or inferior, various in the ſtructure and number of its cells.

The learned author, by his ſubſequent remarks and explanations, is evidently aware of the difficulties attending this claſs, which indeed is in no ſenſe really a natural one, its orders having little or no affinity to each other, except the two laſt *Amentaceæ* and *Coniferæ*.

The characters of the order of *Euphorbiæ* are, *Flowers* monoecious or dioecious, or rarely hermaphrodite. *Calyx* of each tubular, or deeply divided, ſimple or double, the internal ſegments occaſionally reſembling petals. *Petals* none, except the ſegments juſt mentioned. *Stamens*, in the male flowers, definite or indefinite in number, their filaments inſerted either into the receptacle, or the centre of the calyx, diſtinct or united, ſometimes branched, ſometimes jointed. In ſome there are chaffy ſcales between the filaments. *Germen*, in the female flowers, ſolitary, ſuperior, ſeſſile or ſtalked; ſtyles in ſome caſes ſeveral, often three, with an equal number of cells to the capſule, each containing one or two ſeeds; in others the ſtyle is ſimple, with three or more ſtigmas, the fruit of ſeveral

veral cells, equalling the ſtigmas in number, with one or two ſeeds in each. In all the cells are furniſhed with two internally elaſtic valves; the ſeeds have a partial covering, and are attached at the upper part to the permanent central axis of the fruit. Corculum flat, enveloped in a fleſhy albumen. The plants are either herbaceous, or ſhrubby, or arboreſcent; ſome of them milky. Leaves alternate or oppoſite, (in ſome few inſtances wanting,) either with or without ſtipulas. The firſt ſection conſiſts of ſuch genera as have ſeveral ſtyles, moſtly three. Theſe are *Mercurialis*, *Euphorbia*, *Argythamnia* of Browne's Jam. 338. Sw. Prod. 39, *Cicca*, *Phyllanthus*, *Xylophylla*, *Kirganelia*, *Kiggellaria*, *Clutia*, *Andrachne*, *Agyneia*, *Buxus*, *Securinega* of Commerſon, *Adelia*, *Mabea*, Schreb. 641, *Ricinus*, *Jatropha*, *Dryandra*, *Aleurites*, *Croton*, *Acalypha*, *Caturus* and *Excæcaria*. The ſecond ſection, with a ſolitary ſtyle, contains *Tragia*, *Stillingia*, *Sapium of* Browne, *Hippomane*, *Ægopricon*, *Sechium* of Browne, *Hura*, *Omphalea*, *Plukenetia* and *Dalechampia*.

The ſeeds of theſe plants are mild and eatable in many inſtances, if freed from their integuments and corculum, the latter being very dangerouſly purgative, as in *Euphorbia* and even *Ricinus*, proving mild in the latter only from the copious oil of the cotyledons. *Euphorbia*, which gives its name to this natural order, can only by a very bold analogy, or rather hypotheſis, be ſaid to have no corolla, and is very imperfectly polygamous, not monoecious; indeed Juſſieu allows it to be hermaphrodite. See EUPHORBIA.

EUPHORBIUM, is a moſt acrid gum reſin, which exudes from the *Euphorbia officinarum* and other ſhrubs of the ſame genus, and was formerly uſed in pharmacy, but is now nearly, if not, entirely rejected.

This gum is brought from Barbary and other parts of the Mediterranean in tears or drops of an irregular form, generally entangling much impurity; of a pale yellow colour without, and white within. Euphorbium has no ſmell: when taken into the mouth it gives at firſt no taſte, but after a little time a moſt acrid biting ſenſation is felt, which increaſes to an intolerable degree, and if not immediately rejected it proceeds to corrode the ſkin of the tongue and fauces. The ſame acrimony is ſhewn when applied to the body in any other manner. In reducing it to powder the duſt that flies off will excite the moſt violent ſneezing, and often bleeding from the noſtrils and throat, ſo that particular precautions muſt be taken. When laid for ſome time on the ſkin it bliſters.

The ſpirituous tincture of euphorbium is ſtill more acrid.

This gum reſin, on account of its extreme acrimony, can hardly be uſed with ſafety as an internal medicine, as it is liable to produce violent diarrhœa and bloody ſtools, and much inflammation. The only purpoſe for which it has been employed in the later diſpenſatories has been in mixture with cantharides to increaſe the veſicating and irritating property, but euphorbium is now altogether diſuſed.

EUPHORIA, in *Botany*, ſo named by Commerſon from ευφορος, *fertile*, a genus comprehending the two Chineſe fruits Lit-chi and Longàn, to which Juſſieu ſuſpects Forſter's *Pometia* may alſo belong. See SCYTALIA.

EUPHORY, ſignifies the ſame as *Eucracy*.

EUPHRASIA, in *Botany*, from ευφραινω, *to exhilarate*, or *delight*, alluding to the brightneſs or gaiety of the bloſſoms. Eye-bright. Linn. Gen. 304. Schreb. 401. Willd. Sp. Pl. v. 3. 192. Tournef. t. 78. Sm. Fl. Brit. 650. Mart. Mill. Dict. v. 2. Juſſ. 100. Gærtn. t. 54. Claſs and order, *Didynamia Angioſpermia*. Nat. Ord. *Perſonatæ*, Linn. *Pediculares*, Juſſ.

Gen. Ch. *Cal.* perianth of one leaf, inferior, cylindrical, four-cleft, equal, permanent. *Cor.* of one petal, ringent; tube as long as the calyx; upper lip concave, notched; lower ſpreading, deeply three-lobed, its lobes equal, obtuſe, notched. *Stam.* Filaments four, thread-ſhaped, ſituated cloſe under the upper lip; anthers of two lobes, the lobes unequally ſpinous at their lower extremities. *Piſt.* Germen ſuperior, ovate; ſtyle thread-ſhaped, agreeing in form and ſituation with the ſtamens; ſtigma obtuſe, undivided. *Peric.* Capſule ovate-oblong, compreſſed, of two cells and two valves; the partition contrary to the valves. *Seeds* numerous, minute, roundiſh, longitudinally ſtriated.

Eſſ. Ch. Calyx cylindrical, four-toothed, equal. Upper lip of the corolla cloven; lower three-lobed, the lobes cloven. Anthers bearded with unequal ſpines. Capſule ovate-oblong. Seeds ſtriated.

Botaniſts are not perfectly agreed about the limits of this genus, and its near allies *Bartſia* and *Rhinanthus*. The firſt of Willdenow's twelve ſpecies, E. *latifolia*, Linn Sp. Pl. 841, is *Bartſia latifolia*, Sm. Prod. Fl. Græc. Sib. 428, a beautiful native of the ſouth of Europe. His ſixth, E. *odontites*, is *Bartſia odontites* of Hudſ. Fl. Angl. 268, and Sm. Fl. Brit. 648. Engl. Bot. t. 1415.

E. *officinalis*, Linn. Sp. Pl. 841. Engl. Bot. t. 1416. Curt. Lond. faſc. 5. t. 42. common in heathy and mountainous paſtures, which its gay bloſſoms greatly enliven in autumn, is a genuine and original example of the genus. This is a ſmall, upright, annual plant, with ovate ſharply ſerrated *leaves*. The *flowers* are white, ſtrongly ſtreaked with purple, having a yellow ſpot on the lip. On the Alps they are often larger, light purple, and ſtill more beautiful.

The dazzling brilliancy of theſe little bloſſoms ſeems to have given riſe to the vulgar opinion, that the plant was good for the eyes; whence its Engliſh name Eye-bright.

EUPHRATENSIA, in *Ancient Geography*. See COMMAGENE.

EUPHRATES of Alexandria, in *Biography*, a Stoic philoſopher, who flouriſhed in the ſecond century, was a friend of Dio and of Apollonius Tyanæus, who introduced him to Veſpaſian. Although a violent quarrel aroſe between the latter philoſopher and Euphrates, in conſequence of which Philoſtratus, the panegyriſt of the former, inveighs with great ſeverity againſt the latter, it appears from the teſtimony of Epictetus, Pliny the younger, and Euſebius, that Euphrates was univerſally eſteemed for his talents and virtues, and that the cenſures of Philoſtratus deſerve only contempt. Pliny's character of him is highly intereſting. "If ever," ſays he (Ep. l. i. ep. 10.), "polite learning flouriſhed at Rome, it certainly does at preſent. Of this I could give you many inſtances; but I will content myſelf with naming only Euphrates the philoſopher. When, in my youth, I ſerved in the army in Syria, I had an opportunity of converſing familiarly with this excellent man, and took ſome pains to gain his affection, though that indeed was not difficult; for he is exceedingly open to acceſs, and full of that gentleneſs of manner which he teaches. Euphrates is poſſeſſed of ſhining talents, which cannot fail to intereſt even the unlearned. He diſcourſes with great accuracy, dignity, and elegance; and frequently riſes into the ſublimity and luxuriance of Plato himſelf. His ſtyle is copious and diverſified, and ſo wonderfully ſweet, as to captivate even the moſt reluctant auditor. Add to all this, his graceful form, comely aſpect, long hair, and large white beard; circumſtances which, though they may probably be thought trifling and accidental, contribute, however, to procure him much reverence. There is no diſguſting negligence in his dreſs; his countenance is grave, but not auſtere; his approach commands reſpect, without exciting awe.

With the ſtricteſt ſanctity, he unites the moſt perfect politeneſs of manner. He inveighs againſt vice, not againſt men; and, without chaſtiſing, reclaims the offender. You liſten with fixed attention to his exhortations, and even when convinced, ſtill hang with eagerneſs upon his lips."

In conformity to the principles of the Stoic philoſophy, Euphrates, when he found his ſtrength worn out by diſeaſe and old age, voluntarily put a period to his life by drinking hemlock, having firſt, for ſome unknown reaſon, obtained permiſſion from the emperor Adrian. Brucker's Hiſt. Phil. by Enfield, vol. ii.

EUPHRATES, the reputed founder of a religious ſect in the ſecond century, ſometimes called "Ophians," or "Ophites," and ſometimes "Serpentinians," names derived from the peculiar tenet which he held, that the ſerpent, by which our firſt parent was deceived, was either Chriſt himſelf, or "Wiſdom" concealed under the form of that animal, and that he was the occaſion of all the knowledge which men had received. Hence he is ſaid to have inculcated a particular veneration for the ſerpent, preſerving a living one, offering to it a ſubordinate kind of divine honour, and bringing it out to partake of or to conſecrate the euchariſt. Origen and others contend that the followers of Euphrates were not Chriſtians, but calumniators of Jeſus Chriſt, and oppoſers of his doctrine: but Dr. Lardner, who has taken ſome pains in inveſtigating the ſubject, conſiders them as believers in Chriſtianity, and maintaining that Jeſus, who was born of a virgin, was a moſt excellent man, and that, having by his miracles and inſtructions manifeſted himſelf to be the true Meſſiah, was crucified, and afterwards raiſed from the dead, received into heaven, where he ſits on the right hand of God. He conceives that what ſome have ſaid of them, reſpecting the ſerpent being Chriſt, muſt be a miſtake, founded on an opinion that the brazen ſerpent in the wilderneſs was a type or figure of Chriſt. The other accounts of worſhipping the ſerpent, &c. this judicious and learned writer rejects without heſitation. Moreri. Lardner.

EUPHRATES, in *Ancient Geography*, one of the moſt conſiderable and beſt known rivers of Aſia, the ſource of which was in the mountains of Armenia north of Abus, which after receiving ſeveral ſtreams in this part of Armenia, at the towns of Elegia, Gymnias, and Brapus, purſued its courſe towards the ſouth-weſt, ſeparating Armenia Major, on the eaſt, from Armenia Minor on the weſt. It then proceeded ſouth-eaſtward, waſhing the ſkirts of Syria, and dividing Arabia from Meſopotamia; and afterwards directing its courſe towards the north-eaſt, it ſeparated Chaldæa and Babylonia from Meſopotamia, till at length mixing its waters with thoſe of the Tigris, with which it previouſly communicated by ſeveral canals, it emptied itſelf into the Perſian gulf. The Euphrates, according to Ptolemy, above Babylon, near a town in Meſopotamia, called Sipphara, divided itſelf into two branches, one running to Babylon, and the other to Seleucia, where it fell into the Tigris. Pliny ſays the latter was partly artificial; for he places Seleucia at the confluence of the Tigris and Euphrates, adding that the Euphrates was conveyed to it by a canal. Prideaux, on the authority of Pliny, ranks this artificial branch among the ſtupendous works of Nebuchadnezzar. Between theſe two branches a canal was cut from the Euphrates, above Babylon, to the Tigris at Apamea, 60 miles below Seleucia. This canal was denominated *Naarmalcha*, and was dug by Nebuchadnezzar, as Abydenus informs us, to convey the waters of the Euphrates, when it overflowed, into the Tigris, before they reached Babylon. At the diſtance of 800 furlongs from Babylon to the ſouth was another canal, called by Arrian Pallacopes, and by Appian Pallacotta, derived from the branch of the Euphrates that paſſed through Babylon, and continued to certain lakes or marſhes in Chaldæa. On this canal, or river, as Arrian calls it, Alexander ſailed from the Euphrates to the above-mentioned lakes. But it is impoſſible, at this diſtance of time, and after the changes that have occurred, to trace out the numerous branches and canals which watered the ancient country of Babylon. This great river moved ſlowly through a great part of its courſe, and was ill adapted for navigation, as ſome parts of it were ſhoal and others rocky. Thevenot, however, is of opinion, that the Euphrates might, with little trouble, be made navigable, even by great barks, quite to the Tigris, only by clearing the channel of the ſtones with which it is choked in ſome places. The ancient mode of navigating this river was very extraordinary. The veſſels were round, without diſtinction of head or ſtern, and no better than great wicker baſkets, covered over with hides, guided by two oars or paddles. They were capable of carrying a very conſiderable weight; and when they had unloaded their cargo at Babylon, they were ſold, but the hides were kept: and loading their aſſes with them, the navigators returned home by land, the rapidity of the ſtream not allowing them to return by water.

EUPHRATES, in *Modern Geography*, a river of Aſiatic Turkey, which riſes from the mountains of Armenia, as ſome have ſaid, in two ſtreams, a few miles to the N.E. of Erzeron, the ſtreams uniting to the S.W. near that city; and chiefly purſuing a S.W. direction to Semiſat, where it would fall into the Mediterranean, if not prevented by a high range of mountains. In this part of its courſe the Euphrates is joined by the Morad, a ſtream almoſt doubling in length that of Euphrates, ſo that the latter river might more juſtly be ſaid to ſpring from mount Ararat, about 160 Britiſh miles to the eaſt of the imputed ſource. At Semiſat, the ancient Samoſata, this noble river aſſumes a ſoutherly direction; then runs an extenſive courſe to the S.E., and after receiving the Tigris, falls by two or three mouths into the gulf of Perſia, about 50 miles S.E. of Baſſora. N. lat. 29° 50'. E. long. 66° 55'. The comparative courſe of the Euphrates may be eſtimated at about 1400 Britiſh miles. This river is navigable for a conſiderable diſtance from the ſea. This river in its courſe ſeparates Aladulia from Armenia, Syria from Diarbekir, and Diarbekir from Arabia, and paſſing through the Arabian Irak, there joins the Tigris.

EUPHRATES, a river of Africa, in the country of Whidah, on the Slave coaſt.

EUPHROSYNE, in *Mythology*, one of the three Graces. See GRACES.

EUPHROSYNUM, in *Botany*, a name uſed by Pliny and ſome others for the common borrage. See BORRAGE.

EUPILIS, in *Ancient Geography*, *Puſſiano*, a lake of Italy, in Gallia Ciſalpina, whence, according to Pliny, iſſued the river Lambrus.

EUPNŒA, of ευ, *well*, and πνεω, *I breathe*, in *Medicine*, is a right and natural reſpiration.

EUPOLIS, in *Biography*, an Athenian who flouriſhed B.C. 440, was known as a comic writer, and one of that claſs who marked out by name the objects of their ſatire, which rendered him extremely popular with the many, as he was dreaded by the great. He is mentioned by Horace and Quintilian, who put him in the ſame claſs with Cratinus and Ariſtophanes. His comedies were of a political caſt, in one of which Alcibiades was ſo ſeverely attacked, that he is ſaid to have hired aſſaſſins to throw him into the ſea. The plot did not ſucceed, for Eupolis wrote ſeveral comedies after the period aſſigned to this fact, and Ælian relates that he died at Ægina. Fragments of his works have come down to us, and titles of twenty of his plays. Gen. Biog.

EUPORIA, in *Ancient Geography*, a town of Macedonia, placed by Ptolemy in Biſaltia.

Euporia, of ευ and πορος, *paſſage*, in *Medicine*, is an eaſy preparation of medicines, or the eaſineſs of their operation.

EUPSYCHIANS. See Eunomioeupsychians.

EURA, in *Geography*, a town of Sweden, in the government of Abo; 17 miles N.E. of Abo.

EVRA, a town of Abyſſinia; 12 miles S.E. of Siré.

EVRACMINNA, a town of Sweden, in the government of Abo; 17 miles S. of Biorneborg.

EVRAN, a town of France, in the department of the North Coaſts, and chief place of a canton in the diſtrict of Dinan, four miles S. of it. The place contains 3573, and the canton 9175 inhabitants, on a territorial extent of 117½ kiliometres and ſeven communes.

EURAN Islands, a cluſter of ſmall iſlands, on the eaſt ſide of the gulf of Bothnia. N. lat. 63° 54′. E. long. 22° 39′.

EURANIUM, in *Ancient Geography*, a town of Aſia Minor, in Caria.

EURE, in *Geography*, a river of France, which has its ſource in the foreſt of Logny, and terminates in the Seine, above Pont de l'Arche. Its courſe is northward, and extends 36 leagues.

Eure, formerly *Ouche*, a department of the ſecond or northern region of France, in 49° N. latitude, bounded on the north by the department of the Lower Seine, on the eaſt by that of the Oiſe, on the ſouth by the departments of the Eure and Loire and the Orne, and on the weſt by the department of the Calvados. It takes its name from the river Eure, which traverſes it; and its capital is Evreux. It contains 307 ſquare leagues, and 415,574 inhabitants in five diſtricts, *viz.* Fontaudemer, Louviers, Les Andelys, Evreux, and Bernay, 35 cantons, and 843 communes. Its fertile ſoil yields grain, hemp, flax, and paſtures; and it has conſiderable foreſts.

Eure *and Loire*, a department of the ſecond or northern region of France, in 48° 15′ N. lat. compoſed of a part of *Beauce* and of *Perche*, bounded on the N.W. by the department of the Eure, on the eaſt by the departments of the Seine and Oiſe and the Loiret, on the ſouth by the departments of the Cher and Loiret, and on the weſt by the departments of the Orne and Sarte. It takes its name from the rivers Loire and Eure, which water it; and its capital is Chartres. It contains 300 ſquare leagues, and 259,967 inhabitants. It is divided into four diſtricts, *viz.* Nogent-le-Rotrou, Chartres, Chateaudun, and Dreux; 23 cantons, and 460 communes. This department, on account of its great fertility, is called the granary of Paris, and it abounds in fruits and rich paſtures

EVRE, or Yevre, a river of France, which diſcharges itſelf into the Cher by two ſtreams, one near Vierſon, the other at Bourges.

EVRECY, a town of France, in the department of the Calvados, and chief place of a canton in the diſtrict of Caen; ſeven miles S.W. of Caen. The place contains 850, and the canton 13,110 inhabitants, on a territorial extent of 145 kiliometres, and 29 communes.

EVREGNIES, a town of France, in the department of Jemmappe; nine miles N.N.W. of Tourney.

EUREOS, in *Natural Hiſtory*, the name of a ſtone, deſcribed by Pliny, and ſeeming plainly to be the ſame with the tecolithus, which he mentions in another place, and to be the ſtone now called *lapis Judaicus*, and known at this time to be the petrified ſpine of a ſort of echinus marinus, or ſea urchin.

EVREUX, Mediolanum, *Eborice*, or *Civitas Evevigorum*, in *Geography*, a town of France, in the department of the Eure, of which it is the capital, and chief place of a diſtrict. Its north diviſion contains 4200, and the canton 10,458 inhabitants, and the ſouth diviſion 4226, and its canton 10,853 inhabitants; the territorial extent comprehends 345 kiliometres, and each diviſion includes 30 communes. Before the revolution this was the ſee of a biſhop, ſuffragan of Rouen; containing nine pariſh churches, two abbies, and ten convents. This is an ancient and conſiderable town, with large ſuburbs, ſituated in a deep and fruitful vale on the river Eton, 23 miles N.W. from Paris. Its cathedral is a fine Gothic ſtructure. The manufactures of Evreux conſiſt of woollen and linen cloth, and its trade of rice, grain, wine, and cyder; but they are not conſiderable. N. lat. 49° 2′. E. long. 1° 15′.

EURIA, in *Ancient Geography*, a town of Greece, in Epirus.

EURIPIDES, in *Biography*, the contemporary and rival of Sophocles, and one of the moſt ancient Greek tragedians, was born in the iſle of Salamis, in the firſt year of the 75th olympiad, B C. 480, according to many writers, though the Arundelian marble places his birth five years earlier. His father's name was Mneſarchus, an Athenian, and that of his mother was Clito, a ſeller of herbs, according to the report of Ariſtophanes, the avowed enemy of Euripides; but by the teſtimony of later grammarians, founded on the authority of Philochorus, an ancient writer, ſhe was of noble deſcent. Before the birth of his ſon, Mneſarchus is ſaid to have conſulted the oracle of Apollo concerning his future deſtiny, and to have received for anſwer, "that the child who ſhould be born to him would reach the ſummit of glory, and gain the honour of the ſacred garland," which was underſtood to ſignify the crown of victory at the olympic games. When Greece was invaded by Xerxes, Mneſarchus and his wife retired for ſafety, among other Athenians, to the iſland of Salamis. In the autumn of the year 480 B.C. when this invaſion took place, the fate of Greece was in a great meaſure decided by the naval victory of Salamis over the Perſians; and on the ſame day, it is ſaid, Euripides was born, who in memory of this battle, fought in the narrow channel, or *Euripus*, which divides Salamis from the continent, received his name. Euripides, at ſubſequent periods of his life, was accuſtomed to frequent the iſland of his nativity, where was ſhewn a cave, in which ſome of his tragedies are ſaid to have been compoſed. Euripides, in conformity to the ſuggeſtion of the oracle, and alſo to the cuſtom of the country, qualified himſelf for honourable and ſucceſsful conteſt at the public games, by an early initiation in the uſual gymnaſtic exerciſes; but his views were directed to nobler purſuits. Accordingly, whilſt he paid ſome attention to the art of painting, he ſtudied rhetoric under Prodicus, celebrated for the allegory of the choice of Hercules, preſerved by Xenophon, and received inſtructions in phyſics from Anaxagoras, and in morals from Socrates. In his 18th year he firſt applied himſelf to the compoſition of tragedies, the number of which, during the courſe of his life, amounted, as ſome ſay, to 75, but according to others, to 92. He does not appear, however, to have been very ſucceſsful in his exhibitions on the theatre, for no more than five of his performances gained the prize at the olympic games: but they were privately read with avidity and highly applauded by his countrymen. To this purpoſe we may mention the following fact. After the unfortunate expedition of the Athenians againſt Syracuſe, ſeveral captives were kindly treated by the Sicilians, and obtained relief from indigence and wretchedneſs, by going about from place to place, reciting and ſinging the verſes of Euripides. Upon their return to their own country, the poet received their perſonal acknowledgments. Socrates was the friend of Euripides, and is ſaid to have given him advice and aſſiſtance in the compoſition of ſome of his dramas; and he occaſionally attended the public exhibition of them. In the character of Palamedes the poet was ſuppoſed to have delineated that of Socrates; and ſome verſes are quoted addreſſing the Greeks as having ſlain the beſt and wiſeſt of their nation, which the audience applied to the fate of this philoſopher, burſting into tears at the recollection of their crime. As Socrates had become an object of public perſecution and calumny before the repreſentation of the Palamedes, ſome application of the character to his circumſtances might probably have been intended by the poet. But his death could only be alluded to by way of probable anticipation, as he ſurvived Euripides ſome years. The remarkable effect aſcribed to the paſſage of the Palamedes juſt mentioned might poſſibly have taken place at ſome repreſentation of that play ſubſequent to the death of Socrates. Euripides was the conſtant rival of Sophocles, and their mutual jealouſy ſeems to have degenerated into declared enmity. Our poet was frequently the object of raillery to Ariſtophanes. Euripides was twice married; but as he was diſappointed in his expectation of domeſtic happineſs, he is ſaid to have indulged a kind of antipathy to women, for which this circumſtance has been pleaded as an apology. Hence he obtained the name of Μισογυνης, *woman-hater*, though his editor, Barnes, ſtrenuouſly defends him from the charge implied in this appellation, obſerving, that if he has deſcribed ſome females with all the vices incident to human nature, yet he has delineated many others with all the virtues that can adorn their ſex; and Sophocles is ſaid to have obſerved, that the hatred which he expreſſed againſt women was confined to the ſtage. In advanced life he enjoyed ſo little felicity at Athens, that he accepted an invitation to the court of Archelaus, king of Macedonia, where he was honourably treated, though he did not altogether eſcape the effects of malicious jealouſy. To the conſequence of a quarrel from this cauſe ſome have aſcribed his tragical death; for as he was walking in a wood, the king's hounds were let looſe upon him, and tore him in pieces. Others ſay that his death was owing to natural decay. He died at the age of about 75 years. The Athenians ſent embaſſadors to Macedonia, to requeſt the removal of his body to his native country; but Archelaus refuſing to comply with their requeſt, cauſed him to be interred with great magnificence, and erected in honour of him a noble monument in the vicinity of Pella, his chief city. The Athenians appointed a public mourning on occaſion of his death, and erected in memory of him a cenotaph on the road leading from the city to the Piræus. The following epitaph is aſcribed to Thucydides, the hiſtorian.

> "Μνημα μεν Ελλας απασ᾽ Ευριπιδου· οστεα δ᾽ισχει
> Γη Μακεδων, ἡ γαρ δεξατο τερμα βιου.
> Πατρις δ᾽Ελλαδος Ελλας Αθηναι· πλειστα δε Μουσαις
> Τερψας, εκ πολλων και τον επαινον εχει."

"All Greece is the monument of Euripides; the Macedonian land poſſeſſes his bones, for there he reached the boundary of his life. His country is Athens, the Greece of Greece; having afforded general delight by his muſe, he enjoys the recompence of general praiſe."

It has been recorded to the reproach of Euripides, that many of the maxims which he attributes to his dramatic characters are favourable to vice; and though he cannot be wholly exculpated from this charge, he abounds with moral maxims, expreſſed in noble and elegant language, which deeply impreſs the mind of the reader. He has been alſo charged with moroſeneſs of temper; but however this be, he introduces numerous paſſages of tender and delicate pathos. As a tragedian, when compared with Sophocles, it ſeems to be the general opinion, that with leſs pomp of diction, leſs force and elevation of character, and leſs knowledge of dramatic effect than his rival, he more excels in tenderneſs, ſuavity, and moral ſentiment. Ariſtotle calls him the "moſt tragical" of all the poets, meaning either that he was the moſt ſkilful in the drama, or the moſt pathetic. Euripides, it ſhould be recollected, was the favourite poet of Milton. Poſſeſſing a high notion of the preceptive office of the theatre, he was once deſired by the auditors to retrench a paſſage in one of his plays, but he ſtepped forward and ſaid, "I do not write in order to learn from you, but to teach you." Of his works nineteen compleat plays, and the commencement of a twentieth, are ſtill remaining. Of theſe, both ſingly and collectively, there are ſeveral editions. The beſt of the whole works are thoſe of Baſil, 1551, of Plantin, 1571, of Commelin, 1597, of Paul Stephens, 1604, 1611, of Barnes, *Camb.* 1694, and of Muſgrave, Oxf. 1778. Bayle. Moreri. Barnes. Gen. Biog.

EURIPUS, Ευριπος, in *Hydrography*, properly ſignifies a certain ſtrait of the ſea which divides Eubœa from Attica, Bœotia, and Locris, where the currents are ſo ſtrong that the ſea is ſaid to ebb and flow ſeven times a day; in which place, as the ſtory commonly goes, Ariſtotle drowned himſelf out of chagrin, for not being able to account for ſo unuſual a motion. This ſtrait was ſo narrow overagainſt Chalcis as ſcarcely to admit a galley. It is now called the gulf of Negropont.

Euripus has ſince become a general name for all ſtraits, where the water is in great motion and agitation.

The ancient circuſes had their Euripi, which were no other than pits or ditches, on each ſide of the courſe, into which it was very dangerous falling with their horſes and chariots as they ran races. The term Euripus was more particularly applied by the Romans to three canals or ditches which encompaſſed the circus on three ſides, and which were filled occaſionally, to repreſent naumachiæ or ſea-battles.

The ſame people called their ſmaller fountains or canals in their gardens Euripuſes; and their largeſt, as caſcades, &c. *Niles.*

EUROCLYDON, of Ευρος, *eaſt-wind*, and κλυδων, *wave*, is a ſpecies of wind, of which we have an account only in Acts, xvii. 14. and concerning the nature of which critics have been much divided. Bochart, Grotius, Bentley, and others, ſubſtitute another reading, ſupported by the Alexandrian MS. and the Vulgate, *viz.* Ευρακυλων, or *Euroaquilo*; but Mr. Bryant defends the common reading, and conſiders the Euroclydon, *i. e.* Ευρος κλυζων, as an eaſt-wind that cauſes a deep ſea or vaſt inundation. He maintains, in oppoſition to Dr. Bentley's reaſoning, who ſuppoſes that the mariners in the ſhip, the voyage of which is recited in this paſſage, were Romans, that they were Greeks of Alexandria, and that the ſhip was an Alexandrine ſhip, employed in the traffic of carrying corn to Italy; and therefore, that the mariners had a name in their own language for the particular typhonic or ſtormy wind here mentioned. He alſo ſhews from the paſſage itſelf, that the tempeſtuous wind called Euroclydon, beat (κατ᾽ αυτης) upon the iſland of Crete; and therefore, as this is a relative expreſſion, referring to the ſituation of the perſon who ſpeaks of it, who was at that time to the windward, or ſouth of it, the wind blew upon ſhore, and muſt have come from the ſouth or ſouth-eaſt; which, he adds, is fully warranted from the point where the ſhip was, and the direction it ran in afterwards, which was towards the north and north-weſt. Bryant's Obſervations, &c. 1767, p. 1. &c.

EURO-AUSTER. }
EURO-*Notus.* } See WINDS.

EUROMA, in *Ancient Geography*, a town of Aſia, in Phœnicia.

EUROMUS, a town of Aſia, in Caria; ſituated E. of mount Grius, N. of mount Latmus, and N.W. of the town of Mylaſa. It had a theatre and a magnificent temple.

EVRON, in *Geography*, a town of France, in the department of the Mayenne, and chief-place of a canton, in the diſtrict of Laval; 15 miles E.N.E. of Laval. This place contains 4044 and the canton 13,213 inhabitants, on a territorial extent of 205 kiliometres and 11 communes. The fairs of this town are frequented.

EUROPA, in *Mythology*, daughter of Agenor, king of Phœnicia, by his wife Telaphaſſa, who was ſo beautiful, that, according to the fable, Jupiter is ſaid to have fallen in love with her, and to have ordered Mercury to convey her to the ſea-ſhore, where that god, having transformed himſelf into a bull, took her upon his back, and tranſported her into Crete. Some have explained this fable by alleging that a captain of Candia, named Taurus, carried off that princeſs, after he had taken the city of Tyre from Agenor; but others, with greater probability, aſſert, that ſome merchants of Crete, having arrived upon the coaſts of Phœnicia, and ſeen the young Europa, were ſo much ſtruck with her beauty, that they carried her off for their king Aſterius; and as their ſhip bore upon the fore-caſtle a white bull, and that king of Crete had aſſumed the name of Jupiter, it was hence fabled that the god had transformed himſelf into a bull, in order to carry off the princeſs. Aſterius is ſaid to have married her, and to have had by her three ſons; after which ſhe is reported to have engaged the attachment and eſteem of the Cretans to ſuch a degree, that they worſhipped her after her death as a divinity. They even inſtituted a feaſt in honour of her, which was called Hellotia. They afterwards gave her the ſurname of Minerva, and celebrated to her honour that feſtival which was conſecrated to that goddeſs among the Cretans. Several authors have been of opinion that Europe took its name from this princeſs: but the learned Bochart believes that this part of the world was ſo denominated from the whiteneſs of its inhabitants. M. Gebelin, however, deduces the name of Europa from *Wrab*, ſignifying Occidental, and expreſſing its ſituation with regard to Aſia.

EUROPA *rocks*, in *Geography*, rocks in the ſtrait of Mozambique. S. lat. 21° 30′. E. long. 40° 16′.

EUROPE, one of the four grand diviſions, or quarters, as they have been ſomewhat improperly called, of the terraqueous globe. Although Europe be leſs conſiderable in extent than Aſia, or America, or even Africa, it claims on a variety of accounts our more particular attention. In modern times it has been the ſeat of literature and ſcience; in this part of the globe every kind of cultivation and improvement has made the moſt rapid progreſs, and it has been diſtinguiſhed, not only by the general temperature of its climate, the fertility of its ſoil, and the abundance of its productions for the ſupply of neceſſity and the gratification of luxury, but more eſpecially for the wiſdom, ſtrength, and courage of its inhabitants, and for the excellence of its government, laws, and religion. The boundaries of Europe were very inaccurately aſcertained by the ancient geographers, and the name itſelf ſeems to have originated in a ſmall diſtrict near the Helleſpont. More than a third part of Europe, towards the north and eaſt, has only been known with preciſion in modern times. It lies chiefly in the temperate zone, north of Africa, and north-weſt of Aſia, between 35° 25′ and 71° 23′ N. lat. and between 9° 40′ W. and 61° 5′ E. longitude. From the Portugueſe cape, denominated by our mariners the rock of Liſbon, in the weſt, to the Uralian mountains in the eaſt, the length may be about 3,300 Britiſh miles; and the breadth from Cape Nord in Daniſh Lapland to Cape Matapan, the ſouthern extremity of Greece, may be about 2,350. The contents in ſquare miles have been variouſly eſtimated, but at a medium may be ſtated at about 2½ millions. On the ſouth, Europe is bounded by the Mediterranean ſea, on the weſt by the Atlantic, which contains the moſt remote European iſlands, the Azores and Iceland, Greenland being regarded as a part of North America. On the north the boundary is the Arctic ocean, comprehending the remote iſles of Spitzbergen, and Novaya Zemlia, or the New Land. "Toward the eaſt the limits, (ſays Mr. Pinkerton,) admit of ſome diſcuſſion: the Uralian mountains, a grand natural limit, not extending to the Arctic ocean, the river Cara, which flows into the ſea of Karſhoye, is admitted as a boundary. The Uralian limit extends to about 56′ of N. latitude; to the ſouth of which the grand confines of Europe and Aſia have been ſought in the petty diſtinctions of Ruſſian governments. More natural limits might be obtained by tracing the river Ouſa from its ſource, to its junction with the Belaia. Thence along the Kama to the Volga, which would conſtitute a ſtriking natural diviſion, to the town of Sarepta; whence a ſhort ideal line, the only one admitted in this delineation, will lead due weſt to the river Don, which would complete the unaſcertained boundary; that on the north and weſt of the Euxine being clear and preciſe."

The ancient inhabitants of Europe conſiſted of Celts in the weſt and ſouth; Fins in the north-eaſt; and Laps or Laplanders, reſembling the Samoieds of Aſia in the fartheſt north, who enriched their rude language by adopting that of the more civilized Fins. The ancient inhabitants, who ſeem to have been thinly ſcattered, were driven towards the weſt and north by the Scythians or Goths from Aſia, whoſe deſcendants occupy the greater part of Europe; by the Sarmatians or Slavonic tribes, alſo from Aſia, the anceſtors of the Ruſſians, Poles, &c. and who were accompanied by the Heruli, uſing what is now called the Lettic ſpeech, to be found in Pruſſia, Lithuania, Samogitia, Courland, and Livonia, ſomewhat akin to the Slavonic language, with various ſhades of diſtinction. The colony of Iberi, northern Mauretani, paſſed into Spain at a very early period; and the later acceſſion of Hungarians and Turks from Aſia may likewiſe be commemmorated. The preſent population of Europe is commonly eſtimated at 150,000,000; and though ſome writers have aſſerted that this quarter of the globe was anciently more populous than it is now, the opinion does not ſeem to be well founded. It will not readily be adopted by thoſe who duly conſider the number and magnitude of modern cities, towns, and villages; the abolition of feudal wars; the adoption of a mode of combat leſs deſtructive than that which formerly prevailed; the gradual extirpation of ſuperſtition, fanaticiſm, barbarity, and ſlavery; and the many extenſive improvements made in agriculture, by eradicating foreſts, draining marſhes, cultivating waſtes, and opening canals of communication in the interior countries. It is generally allowed, that, notwithſtanding the ravages of war, and emigrations to foreign parts, the population of moſt European ſtates has been, for ſome time paſt, increaſing. The prevalence of the Chriſtian religion throughout Europe, except in ſome parts of Turkey, has been favourable to knowledge, induſtry, and civilization; and it has contributed to conſtitute the whole of Europe, as it were, into one republic, ſo that any uſeful diſcovery made in one ſtate paſſes rapidly to the reſt. The mutual intercourſe between the different ſtates of Europe is very much facilitated by its inland ſeas, as well as navigable rivers and canals. Of the inland ſeas the principal are the Mediterranean, the Baltic, and the White ſea, which ſee reſpectively. Its other ſeas are the German, often ſtyled the North ſea, the Iriſh ſea, and various parts of the Atlantic. The gulfs and bays of Europe are very numerous, among which we may reckon the following, *viz.* the Bothnian and Finland gulfs; the Murray frith, and Frith of Forth, on the eaſt coaſt of Scotland; the bay of Biſcay, a large inlet of the Atlantic, on the eaſt bounded by France, and on the ſouth by Spain; the gulfs of the Mediterranean, *viz.* that of Lyons, S. of France; that of Genoa, between Corſica and the Genoeſe republic; the gulf of Venice, between Italy and Greece; the gulf of Lepanto, N. of Morea; the Archipelago between Greece and Aſia Minor; the ſea of Marmara between Europe and Aſia; and the ſea of Azoph on the north coaſt of the Euxine. The moſt conſiderable ſtraits are that of Waygatz at the N. E. extremity of Europe; the ſound of Elſinore between the iſland of Zealand and Sweden; the Little Belt between Funen and Jutland; the Categat, or entrance into the Baltic; the ſtrait of Dover, or Engliſh channel, between England and France; the Briſtol channel, between England and Wales; St. George's channel, between Great Britain and Ireland; Pentland frith, between Scotland and the Orkney Iſles; the ſtrait of Gibraltar, between Spain and Africa; the ſtrait of Meſſina, between Italy and Sicily; the Dardanelles ſtrait, or ſouth entrance into the ſea of Marmara; the ſtrait of Conſtantinople, that forms a communication between the ſea of Marmara and the Euxine; and the ſtrait of Caffa, between the Euxine and the ſea of Azoph. The moſt remarkable capes are North Cape, the extreme point of Lapland; Cape Finiſterre, on the N. W. coaſt of Spain; Cape St. Vincent, the S. W. extremity of Portugal; and Cape Matapan, the S. point of the Morea. Its principal lakes are thoſe of Onega, Ladoga, and Peipus, in Ruſſia; thoſe of Geneva and Conſtance, S. W. and N. of Switzerland; Lago Maggiore, and others, in the northern parts of Italy. The largeſt rivers are the Volga, Don, and Dwina, in Ruſſia; the Dnieper on the eaſt border of Poland; the Danube, between Hungary and European Turkey; the Rhine and Elbe in Germany; the Rhone in France; the Po and Tyber in Italy; the Tago in Spain; the Scheldt and Meuſe in the Netherlands; the Thames and Severn in England; the Tay in Scotland, the Shannon in Ireland, &c. &c. The principal chains of mountains are the Carpathian or Krapach mountains, between Poland and Hungary; the Alps, between France, Switzerland, and Italy; the Apennines, in Italy; the Pyrenées between France and Spain; and the extenſive ridge that ſeparates Norway from Sweden. The moſt diſtinguiſhed iſlands are Great Britain and Ireland, the Orkney Iſles, the Hebrides, Zealand, and Funen, in the Baltic; Iceland, in the North ſea; and in the Mediterranean, Ivica, Majorca, Minorca, Sardinia, Corſica, Sicily, Malta, Candia, and the iſlands of the Archipelago.

The principal European ſtates are the Britiſh empire, including England, Scotland, and Ireland; the ſtates of Denmark, comprehending Denmark with the adjacent iſlands, Norway and Iceland; Sweden; Ruſſia, formerly called Muſcovy; Holland; France, including the Netherlands, Italian ſtates, and other late acquiſitions; Switzerland; Germany and Auſtria; Pruſſia; Bohemia and Hungary; Poland, now diſmembered; Spain; Portugal; Sicily; Malta; and Turkey in Europe. See each under its appropriate title.

EUROPEAN Hours. See Hour.

European *Ocean.* See Ocean.

EUROPUS, in *Ancient Geography*, a town of Aſia, in Parthia, founded, as Strabo ſays, by Nicator, and called by the Parthians *Arſacia.*—Alſo, a town of Aſia, in Syria, ſituated on the banks of the Euphrates, E. of Hieropolis, and S. of Zeugma.—Alſo, a town of Aſia, in Caria.—Alſo, a town of Macedonia.—Alſo, a river of Greece, in Theſſaly, which roſe in mount Citarius, and flowed into the Peneus.

EUROTAS, a river of Laconia, which commenced on the frontiers of Arcadia, watered Sparta, and proceeding ſouthward, diſcharged itſelf into the Laconic gulf.—Alſo, a river of Greece, in Theſſaly, near mount Olympus.—Alſo, a river of Italy, near Tarentum, the ſame with the river Galeſus, according to Polybius.

EURUS, in *Mythology*, the genius of the ſouth-eaſt wind, according to the Grecian diviſion of the compaſs into eight points; but according to the Roman diviſion into four, Eurus was the intelligence that preſided over the whole eaſtern quarter of the heavens. (See Wind.) "Eurus," ſays Spence, "according to the Roman poets, ſeems to have his character compoſed from the Apeliotes and Eurus of the Greeks: by one deſcription of him he ſhould have a look that ſeems delighted, and in another he is ſpoken of as playful and wanton. He is ſometimes deſcribed as impetuous, and ſometimes as diſordered with the ſtorm he has been driving along the ſea. Horace gives us a picture of the former, and Valerius Flaccus of the latter. I ſhould be apt to imagine, from ſome expreſſions in the poets, that he was ſometimes repreſented on horſeback, or perhaps in a chariot, whirling through the air; but there are ſo few remains of the ancient artiſts relating to theſe airy beings, that we have nothing from them to confirm any ſuch conjecture."

EURYA, in *Botany*, ſuppoſed to be from ευρυς, *broad* or *ample*, the application of which to this plant we do not, from any part of the deſcription or figure, perceive. Thunb. Jap. 11. Schreb. 321. Willd. Sp. Pl. v. 2. 856. Mart. Mill. Dict. v. 2. Juſſ. 432. Claſs and order, *Dodecandria Monogynia.* Nat. Ord. uncertain, Juſſ.

Gen. Ch. *Cal.* Perianth inferior, of five ovate, concave, obtuſe, ſmall leaves, with two leſſer ones at its baſe. *Cor.* Petals five, roundiſh-ovate, concave, the ſize of the calyx. Nectary a glandular ring round the baſe of the germen. *Stam.* Filaments thirteen, extremely ſhort; anthers erect, ſquare, almoſt as long as the corolla. *Piſt.* Germen ſuperior, roundiſh, ſmooth; ſtyle awl-ſhaped, ſhorter than the ſtamens; ſtigmas three, reflexed. *Peric.* Capſule globoſe, tipped with the permanent ſtyle, ſmooth, of five valves and five cells, ſcarcely ſo big as a pepper-corn. *Seeds* ſeveral, obſcurely triangular, dotted, brown, deſtitute of pubeſcence.

Obſ. Thunberg obſerved the flowers to be moſt frequently dioecious.

Eſſ. Ch. Calyx double; the inner of five equal leaves; the outer of two ſmaller ones. Petals five. Capſule ſuperior, of five cells and five valves. Seeds numerous.

E. *japonica.* Thunb. Jap. 191. t. 25. (Fiſakaki; Kæmpf. Amœn. Exot. 778.) A Japaneſe ſhrub, common on the hills about Nagaſaki, flowering in September and October, and cultivated in gardens for the ſake of its elegance. It is ſmooth in every part. *Branches* ſlender, alternate, leafy. *Leaves* alternate, ſtalked, elliptic-lanceolate with a blunt point, ſerrated, compared by Kæmpfer to thoſe of tea, evergreen, yellowiſh beneath, an inch or two long. *Flowers* axillary, in pairs, ſtalked, ſmall, white or reddiſh. Thunberg deſcribes the fruit as above; but Kæmpfer ſays "the *berries* reſemble thoſe of juniper, and are juicy, giving a ſtain like ultramarine, and containing from ten to twenty hardiſh brown ſeeds, crackling under the teeth." If Thunberg adverted to this deſcription, he might perhaps deduce the generic name, though incorrectly, from ευ, *well*, and ρυαξ, *a flowing of juice*, or *a falling of berries.*

EURYALE, in *Mythology*, one of the Gorgons, daughter of Phorcys, and ſiſter of Meduſa: ſhe was ſubject neither to old age nor death.

EURYAMPUS, in *Ancient Geography*, a town of Macedonia, in Magneſia.

EURYANDRA, in *Botany*, from ευρυς, *broad*, and ανηρ, *a male*, becauſe the male organs, or ſtamens, are dilated at the ſummit. Forſt. Gen. t. 41. Schreb. 367. Juſſ. 280. See Tetracera; to which genus Schreber, in his emendanda, 833, and Willdenow, Sp. Pl. v. 2. 1242, have at the recommendation of Solander referred it.

EURYDICE, in *Mythology*, the wife of Orpheus, who, flying from Ariſtæus that endeavoured to raviſh her, was ſlain by a ſerpent. Her huſband went down to the ſhades, and by the force of his muſic perſuaded Pluto and Proſerpine to give him leave to carry back his wife; which they granted, provided he did not look on her till he came to the light; but he, breaking the condition, was forced to leave her behind him.

EURYMEDON, in *Ancient Geography*, *Zacuth*, a river of Aſia, in ancient Pamphylia, which had its ſource in mount Taurus, paſſed the town of Aſpenus, and diſcharged itſelf into the ſea of Pamphylia.

EURYMENÆ, a town of Greece, in Theſſaly.

EURYNOME, in *Mythology*, the mother of the three Graces.

EURYNOMIA, Ευρυνομεια, in *Antiquity*, an anniverſary ſolemnity in honour of Eurynome, by ſome thought to be the ſame with Diana, by others one of Oceanus's daughters.

EURYPHON, the Cnidian phyſician, in *Biography*, was a contemporary of Hippocrates, but probably older in years, ſince he is deemed the author of the Cnidian aphoriſms, which are quoted by Hippocrates. Theſe two phyſicians are ſaid by Soranus to have met in conſultation in the preſence of king Perdiccas. Euryphon is mentioned by Plato the comedian, as having produced many ſcars on the ſkin of Cineſias, the ſon of Evagoras, by the employment of actual cauteries for the cure of empyema, or pulmonary conſumption; a practice which Hippocrates purſued. See Le Clerc Hiſt. de la Med.

EURYTHMIA, from ευ and ρυθμος, *order*, an old term in *Surgery*, ſignifying adroitneſs in handling inſtruments.

EURYTHMY, Ευρυθμια, in *Architecture*, *Painting*, and *Sculpture*, a certain majeſty, elegance, and eaſineſs, appearing in the compoſition of divers members or parts of a body, building, or painting, and reſulting from the fine proportions thereof.

The word is Greek, and ſignifies literally a *conſonance* or *fine agreement*, or, as we call it, a *harmony of all the parts*, being compounded of ευ, *well*, and ρυθμος, *rythmus*, *cadence*, or *agreement of numbers*, *ſounds*, or the like things.

Vitruvius ranks eurythmia among the eſſential parts of architecture; he deſcribes it as conſiſting in the beauty of the conſtruction or aſſemblage of the ſeveral parts of the work, which renders its aſpect or whole appearance graceful; *e. gr.* when the height correſponds to the breadth, and the breadth to the length, &c.

"From theſe three ideas or deſigns, *viz.* orthography, ſcenography, and profile, it is that eurythmy, *majeſtica*, and *venuſta ſpecies edificii*, do reſult, which creates that agreeable harmony between the ſeveral dimenſions, ſo as nothing ſeems diſproportionate, too long for this, or too broad for that, but correſponds in a juſt and regular ſymmetry, and conſent of all the parts with the whole." Evelyn's Account of Archit. &c.

EUSCOM, in *Geography*, a river of Canada, which runs into lake St. Clair. N. lat. 42° 45′. W. long. 82° 25′.

EUSDALE, or Eysdale, a ſmall iſland on the W. coaſt of Scotland, noted for its quarries of ſlate. N. lat. 56° 13′. W. long. 5° 48′.

EUSEBES, the name of a ſpecies of marble mentioned by Pliny: he has given us no deſcription of it, but only tells us, that there was a ſeat made of it in the temple of Hercules at Tyre, from which the prieſts pretended that the gods uſed to ariſe.

EUSEBIANS, a denomination given to the ſect of Arians, on account of the favour and countenance which Euſebius, biſhop of Cæſarea, ſhewed and procured for them at their firſt riſe; or rather from the protection afforded to Arius, and the adoption of his opinions by Euſebius biſhop of Nicomedia. See Arians.

EUSEBIUS, pope, in *Biography*, a native of Greece, ſon of a phyſician, perhaps he himſelf at one period was a phyſician, ſucceeded Marcellus in the ſee of Rome. It is believed that he filled the pontificate but a very few months. He was a violent opponent to the re-admiſſion of lapſed Chriſtians to communion, and his conduct on this head created great diſſenſions at Rome, to put an end to which the emperor Maxentius baniſhed him to Sicily. Moreri. Bower.

Eusebius, ſurnamed *Pamphilus*, was born at Cæſarea in Paleſtine, of which he was afterwards biſhop, about the year 270. Of his parents, and his inſtructors in early life, we have no account; nor is any thing recorded concerning his family. His talents and learning may, however, be juſtly appreciated by his numerous and valuable works. Having been ordained preſbyter, probably, by Agapius, biſhop of Cæſarea, he ſet up a ſchool in that city, which produced many learned men, and whilſt he was in this ſituation he formed an intimate acquaintance and friendſhip with Pamphilus, a learned preſbyter of the ſame church, who is ſuppoſed to have afforded him much aſſiſtance in his ſtudies. When Pamphilus was impriſoned in the year 307, Euſebius attended him to animate his fortitude and comfort him in his diſtreſs: and after the martyrdom of his friend in 309, he removed to Tyre, where he witneſſed the firmneſs and patience with which many Chriſtians endured the ſeverity of perſecution. From thence he went to Egypt, where the ſame ſcene was exhibited, and where he himſelf was impriſoned. As he did not ſuffer in common with others, ſome perſons have inſinuated, that he procured his liberty by ſacrificing, or by ſome other mean compliance, unbecoming his Chriſtian principles and profeſſion. But Dr. Lardner has alleged ſeveral circumſtances which evince this accuſation to be altogether unfounded. At the cloſe of the Diocleſian perſecution, Euſebius returned to Paleſtine, and ſucceeded Agapius, according to the more general opinion, as biſhop of Cæſarea in the year 315. It is certain, however, that he was biſhop of Cæſarea in the year 320 at the lateſt. After this period he was preſent at moſt of the ſynods held in that part of the world; and on all occaſions diſtinguiſhed himſelf by recommending peace and mutual forbearance. At the famous council of Nice in 325, he was placed by command of Conſtantine on the right hand of the throne, and opened the meeting by a panegyrical addreſs. At this council he ſeems to have been deſirous of compromiſing the diſpute between Arius, to whoſe ſentiments he probably inclined, and the orthodox party; and with this view propoſed a creed, which all the fathers allowed to be unexceptionable. Some of the moſt zealous partizans, however, ſuggeſted the propriety of introducing the word ὁμοούσιος, or *conſubſtantial*, as applicable to the Son; and the motion for this purpoſe was carried by a majority. Euſebius for ſome time demurred, alleging that the expreſſion was unſcriptural; but at length, being allowed to ſubſcribe to the term in his own ſenſe of it, he ſubmitted; and the word became afterwards the teſt of orthodox belief, but very ineffectual for allaying the diſſenſions of the Chriſtian church. In the year 330 Euſebius concurred with the council at Antioch in depoſing Euſtathius the biſhop; but though the biſhops and people concurred in electing him for this ſee, which was more honourable and profitable than that of Cæſarea, he peremptorily refuſed the acceptance of it. Although they applied to Conſtantine for the interpoſition of his authority, Euſebius wrote to the emperor, and obtained his permiſſion to decline it, accompanied with encomiums on his moderation and diſintereſtedneſs, which he juſtly merited. At the council of Tyre in 335 he joined thoſe biſhops who condemned the proceedings of Athanaſius, biſhop of Alexandria; and he was deputed to attend the emperor, in order to juſtify the meaſures that had been adopted againſt that prelate. On occaſion of this viſit to Conſtantinople, he pronounced his panegyric on the emperor, and obtained ſingular marks of Conſtantine's condeſcenſion and favour. After his return to Cæſarea, the emperor kept up an epiſtolary correſpondence with him, ſpecimens of which are preſerved in Euſebius's life of that prince. This work was written ſoon after the death of the emperor; nor did the biſhop long ſurvive, for he died in the year 339 or 340. Of the learning and application of Euſebius, his works afford ample evidence. "From his works it appears," ſays Tillemont, "that he had read all ſorts of Greek authors, whether philoſophers, hiſtorians, or divines, of Egypt, Phœnicia, Aſia, Europe, and Africa." Euſebius had opportunities for converſing with the moſt learned men of his time, and he had acceſs to the beſt libraries: ſo that from theſe different reſources he was able to compile works of various kinds, in which he exerciſed a laudable caution with reſpect to his authorities and facts, and in which he alſo manifeſts a conſiderable degree of candour and impartiality. His works, however, as compoſitions, claim no very high commendation, as they are deſtitute of elegance and perſpicuity. Upon the whole we may obſerve, that he was a good man as well as a learned ſcholar; zealouſly attached to religion, without bigotry; an enemy to eccleſiaſtical tyranny and diſcord, and always deſirous of accommodating differences, and reconciling contending parties. Nevertheleſs Dr. Lardner mentions with diſapprobation his concurrence with the Arian party in the harſh treatment given to Euſtathius, biſhop of Antioch, Athanaſius of Alexandria, and Marcellus of Ancyra. As to his ſentiments with regard to the doctrine, warmly controverted in his time, Dr. Jortin inclines to think, that he was neither an Arian nor an Athanaſian, but that he endeavoured to ſteer a middle courſe, and yet inclining more to the Arians than to the Athanaſians. Dr. Lardner, with his uſual caution, obſerves, that this is a queſtion which cannot be eaſily decided.

Of the works of Euſebius we can here enumerate only the principal, referring for an account of the reſt to the writers cited at the cloſe of this article. The firſt that deſerves mention is the "Eccleſiaſtical Hiſtory," in ten books, publiſhed in 326, and containing the hiſtory of the Chriſtian church from the birth of Chriſt to his own times. The beſt edition is that of Valeſius, publiſhed at Cambridge by Reading in three volumes folio. This contains Euſebius's "Life of Conſtantine," in four books, written in 337 or 338, and other eccleſiaſtical hiſtorians, Socrates, Theodoret, &c. In this hiſtory we have ſeveral paſſages concerning the canon of ſcripture; in which the author treats of the order of the goſpels; of the ſcriptures univerſally acknowledged, and of thoſe that are not ſuch; of the epiſtles, &c. (See Canon.) Euſebius's "Chronicle" was a work of prodigious labour and learning, and is preſerved only in a Latin verſion of Jerome. The "Evangelical Preparation," in 15 books, and ten books of the "Evangelical Demonſtration," which originally comprehended 20 books, are ſtill extant; and contain the moſt learned defence of Chriſtianity againſt both Jews and Pagans, tranſmitted to us from antiquity. A beautiful edition of theſe valuable works was publiſhed in Greek, by Robert Stephens, in 1544 and 1545, in 2 vols. fol., and reprinted at Paris, in 1628, in 2 vols. fol., with a Latin verſion of the former, and various readings from different MSS. and notes by Francis Vigerius, and Donatus's Latin verſion of the latter. Euſebius was alſo the author of a "Commentary upon the 150 Pſalms," publiſhed by Montfaucon in 1705, as far as the 119th pſalm: "A Commentary upon the Prophecies of Iſaiah," publiſhed likewiſe by Montfaucon: "An Expoſition of the Song of Songs," publiſhed by Meurſius in 1627; "A Treatiſe againſt Hierocles" who had made a compariſon of Apollonius Tyanæus with Jeſus Chriſt, ſtill extant in the original Greek; "Two books againſt Marcellus," who revived the hereſy of Sabellius, and "Three books of Eccleſiaſtical Theology," written in 336; "An Apology for Origen," in 6 books, the joint work of Euſebius and Pamphilus, now exiſting in a Latin verſion; "Ten Evangelical Canons," or rules for harmonizing the goſpels; the "Topics," in two books, being a kind of dictionary of places mentioned in the Scriptures; "A deſcription of the Church of the Sepulchre at Jeruſalem, &c." compoſed in 335; "An Oration in praiſe of Conſtantine," which is as much an argument for the truth of the Chriſtian religion, as a panegyric upon the emperor, and much commended by Du Pin and Lardner; the "Life of Conſtantine," in 4 books, already mentioned: "Fourteen ſmall pieces in Latin," publiſhed by James Sirmond in 1643, 8vo. and many other treatiſes, that are no longer extant. Fabr. Bibl. Græc. v. vi. Cave's H. L. vol. i. Lardner's Works, vol. iv. Jortin's Rem. on E. H. vol. ii.

Eusebius, firſt of all biſhop of Berytus in Phœnicia, and afterwards of Nicomedia, in Bithynia, was advanced to the ſee of Conſtantinople in 338 or 339. He was a relation of the emperor Julian, who was educated by him, and probably alſo of Conſtantine: and as he was a man not only diſtinguiſhed by his abilities and learning, but favoured with free acceſs to the court, his influence on behalf of the Arian party, to which he was attached, was always of great importance to their cauſe. From the protection afforded to Arius and his followers by Euſebius they were frequently denominated "Euſebians." Although he remonſtrated againſt the proceedings of the court of Nice in 325, at which he was preſent, he ſubſcribed the creed, probably with the ſame explanation which was given by the biſhop of Cæſarea of the ſame name. That this was the caſe we may infer from the patronage which he afforded to the Arians, and which cauſed Conſtantine to depoſe him from his ſee and to ſend him into exile. He was afterwards, *viz.* in 328 or 329, recalled, and reſtored to his ſee, as well as to the favour of the emperor. Afterwards, when the Arian party became triumphant at the court of Conſtantinople, he encouraged the perſecution of thoſe who had been the perſecutors of Arius. Having maintained his credit and influence with Conſtantine till his death, he gained in an equal, if not greater, degree, the confidence of his ſon Conſtantius; who promoted him, in 338, to the ſee of Conſtantinople. In this high ſtation he was active in promoting the Arian intereſts, and in perſecuting the Catholics. Soon after the council of Antioch, held in 341, probably in the ſame or the ſucceeding year, he terminated his career. Euſebius was eminent for his abilities and learning; and his friends have extolled his piety and virtue: but no ſufficient apology can be offered for his intolerance. His writings were numerous, but none of them remain, except a "Letter concerning Arius and his Opinions," preſerved by Theodoret. Fabr. Bibl. Græc. vol. vi. Cave's H. L. vol. i. Lardner's Works, vol. iv.

Euſebius, biſhop of Emeſa, who flouriſhed about the year 340, was deſcended of a very honourable family, and born at Edeſſa in Meſopotamia, at which place he enjoyed the benefit of a learned education, and of early inſtruction in the ſacred ſcriptures. He afterwards removed to Paleſtine, where he ſtudied under Patrophilus of Scythopolis, and Euſebius of Cæſarea. He likewiſe went to Antioch, and from thence to Alexandria, in which city he ſtudied philoſophy, and then returned to Antioch. Some time after that, having refuſed the offer of the ſee of Alexandria, from which Athanaſius was depoſed in 341, he was appointed biſhop of Emeſa; where his diſtinguiſhed proficiency in literature and the ſciences led the ignorant populace to charge him with the practice of magical arts. Under this accuſation, he was obliged to retire to Laodicea, and to ſeek the protection of George, biſhop of that city, who was afterwards his biographer. When the prejudices of the miſguided people at Emeſa ſubſided, he returned thither, and here he ſpent the greater part of the remainder of his life, which terminated at Antioch about the year 360. He is generally thought to have embraced the Arian tenets: though Cave thinks that he ſhould be ranked among the Semi-Arians. However this be, his character was held in high eſtimation for virtue and piety, as well as for learning and eloquence. Although he was great and good, as Sozomen ſays, he experienced the envy of thoſe who are offended at other men's virtues. The emperor Conſtantius, however, was much pleaſed with him, and his attendance was always required by that prince in his expeditions againſt the Perſians. He wrote a great number of books, which were chiefly treatiſes againſt the Jews, againſt the Novatians, and againſt the Manichæans; 10 books upon the epiſtle to the Galatians; and many ſhort homilies upon the goſpels. His works are in general loſt. His treatiſe againſt the Jews is ſaid to be ſtill extant in a Greek MS. in the library at Vienna. The homilies, that have been publiſhed under his name at Paris in 1575, and at Antwerp in 1602, 8vo. are now allowed to be the productions of other writers. Socr. Hiſt. Eccl. l. iii. Cave's H. L. vol. i. Lardner's Works, vol. iv.

Euſebius, biſhop of Verceil, or Vercelli, in Italy, was born in Sardinia; and flouriſhed about the year 354. In this year he was deputed by pope Liberius to plead the cauſe of Athanaſius, after his expulſion from Alexandria, before the emperor Conſtantius; and in the council at Milan he was a zealous advocate for the depoſed biſhop, and for the Nicene creed. The Arian party, however, prevailed, and a decree was paſſed for condemning the conduct of Athanaſius. Euſebius reſiſted, and for his unyielding ſteadineſs he was baniſhed to Scythopolis in Syria, afterwards to Cappadocia, and laſt of all into the Upper Thebais. The cauſe of orthodoxy, nothwithſtanding all his ſufferings, found him an undaunted and perſevering advocate. Upon the acceſſion of Julian to the empire, he and other friends were allowed to return home; and during the remainder of his life he maintained his invincible attachment to the Catholic doctrine, and his zeal in promoting it. He died about the year 370, or ſoon after. Moſt of his works have been loſt: but it is ſaid that in the cathedral church at Verceil there is a MS., containing a Latin verſion of the four Goſpels, which is inſerted in the "Evangeliarium Quadruplex Latinæ Verſionis Antiquæ, ſeu veteris Italicæ," publiſhed by Joſeph Bianchini, at Rome, in 1749. Cave's H. L. vol. i. Lardner's Works, vol. iv. chap. 90.

Euſebius, biſhop of Dorylæum in Phrygia in the fifth century, was at firſt an eminent advocate at Conſtantinople, but embracing the eccleſiaſtical life, he obtained the above-mentioned ſee, and diſtinguiſhed himſelf by his oppoſition to the Eutychians. Some few of his works remain, which are of a polemical nature, and not worth mentioning. Cave's Hiſt. Lit. vol. i.

EUSENE, in *Ancient Geography*, a town of Aſia, in Paphlagonia. Ptolemy.

EUSHAR, in *Geography*, a town of Aſiatic Turkey, in Natolia; 24 miles E. of Iſbarteh.

EUSHEIM, a town of Germany, in the principality of Wurzburg; 3 miles N.W. of Volckach.

EUSIMARA, in *Ancient Geography*, a town of Aſia, in Melitené, a country of Cappadocia, ſeated on the bank of the Euphrates. Ptolemy.

EUSKIRCHEN, in *Geography*, a town of France, in the department of the Roer; 20 miles S.E. of Juliers.

EUSTACE, or Eustatia, an inconſiderable American iſland, about 20 miles in circuit, forming with a long point of land the entrance to the harbour of St. Auguſtine, in Eaſt Florida. It was alſo called Metanzas, or Slaughter, from a butchery made upon it by the Spaniards.

EUSTACHE, David, in *Biography*, a French proteſtant miniſter, at Montpellier, aſſiſted at the national ſynod held at London in 1659, as deputy of the province of Lower Languedoc, and was nominated by the aſſembly to preſent to the king the letter which they had addreſſed to him. He performed the taſk much to the ſatisfaction of thoſe who had appointed him to the office. He was author of many theological pieces and ſermons; the titles of ſome of the former are "Salutary Remedies againſt a Departure from God;" "The Triumph of Faith;" "An Anſwer to the Queſtion aſked of the Proteſtants, where was your Church before Luther;" "The Orator Tertullus convicted;" which was a reply to the harangue ſuppoſed to be made by the wiſe men of the pretended reformed religion to the queen Maria Thereſa, upon her entrance into the kingdom, in which they declared that being informed ſhe had expreſſed great concern that part of the king her huſband's ſubjects were heretics, they came to leſſen that concern by embracing her majeſty's religion, and that this they did after having been ſatisfied, by the teſtimony of their moſt famous authors, that one may be ſaved in the Romiſh religion. Moreri. Bayle.

EUSTACHIAN Tube, in *Anatomy*, is the paſſage by which air is conveyed from the fauces to the tympanum of the ear, ſo called from an Italian anatomiſt. See Ear.

Eustachian *valve*, is a part formed in the right auricle of the heart. See Heart.

EUSTACHIUS, Bartholomew, in *Biography*, one of the moſt celebrated anatomiſts of the ſixteenth century, was a native of a little village in Italy, called San Severino. He purſued his ſtudies at Rome, where he firſt conceived a bias in favour of medicine, and eſpecially of anatomy, which he cultivated with ſuch ſucceſs, that he was appointed to the profeſſor's chair in that college. This is nearly the ſum of our knowledge reſpecting the life of this celebrated man: he died at Rome in 1574. Euſtachius was the author of ſeveral works, the greater part of which is loſt. His treatiſe "De Controverſiis Anatomicorum," which was one of the moſt conſiderable of his productions, is much regretted. Thoſe of his writings, which remain, conſiſt of his Opuſcula, which appeared under the following titles, "Opuſcula Anatomica, nempe de Renum ſtructura, officio, et adminiſtratione: de auditûs organo: oſſium examen: de motu capitis: de vena quæ azygos dicitur, et de alia, quæ in flexu brachii communem profundam producit: de dentibus." Venet. 1563, and again in 1674, with the notes of Pinus. An edition was alſo publiſhed at Leyden, 1707, under the ſuperintendance of Boerhaave.

Euſtachius was the author of ſeveral diſcoveries in anatomy; he was the firſt who deſcribed the renal capſules, and the thoracic duct; and his name, ſtill attached to the paſſage leading from the throat to the internal ear, (the Euſtachian tube,) announces the origin of our knowledge on that ſubject. A ſeries of figures engraved on copper were mentioned in his Opuſcula as nearly finiſhed; but they were loſt for more than 150 years, and were diſcovered, and publiſhed at Rome in 1714, by Lanciſi, phyſician to pope Clement XI. in one volume folio. Theſe plates were again publiſhed, but not well printed, at Geneva in 1717. The edition of Rome in 1728 is excellent; but the one publiſhed at the ſame city, 1740, by Petrioli, is leſs valuable. The ſame work was twice publiſhed at Leyden, under the direction of Albinus, *viz.* in 1744 and 1762.

Euſtachius edited the lexicon of Erotian at Venice in 1666, under the title of "Erotiani, Græci ſcriptoris vetuſtiſſimi, vocum, quæ apud Hippocratem ſunt, collectio, cum annotationibus Euſtachii," in 4to. Eloy. Dict. Hiſt.

EUSTATHIANS, in *Eccleſiaſtical Hiſtory*, a name given to the Catholics of Antioch in the fourth century, on occaſion of their refuſal to acknowledge any other biſhop beſide St. Euſtathius, biſhop of Sebaſté in Armenia, depoſed by the Arians.

The denomination was given them during the epiſcopate of Paulinus, whom the Arians ſubſtituted for St. Euſtathius, about the year 330, when they began to hold their aſſemblies apart. About the year 350, Leontius of Phrygia, called the Eunuch, who was an Arian, and was put in the ſee of Antioch, deſired the Euſtathians to perform their ſervice in his church; which they accepted; and the church of Antioch ſerved indifferently thus both for the Arians and Catholics.

This, we are told, gave occaſion to two inſtitutions, which have ſubſiſted in the church ever ſince; the firſt was pſalmody in two choirs; though Mr. Baillet thinks, that if they inſtituted an alternate pſalmody between two choirs, it was between two Catholic choirs, and not by way of reſponſe to an Arian choir. The ſecond was the doxology, *Glory be to the Father, and the Son, and the Holy Ghoſt.*

This conduct, which ſeemed to imply a kind of communion with the Arians, gave great offence to abundance of Catholics, who began to hold ſeparate meetings, and thus formed the ſchiſm of Antioch. Upon this the reſt, who continued to meet in the church, ceaſed to be called Euſtathians; and that appellation became reſtrained to the diſſenting party.

St. Flavianus, biſhop of Antioch, in 381, and one of his ſucceſſors Alexander, in 482, brought to paſs a coalition or re-union between the Euſtathians and the body of the church of Antioch, deſcribed with much ſolemnity by Theodoret, Eccl. lib. iii. cap. 2.

Eustathians were alſo a ſect of heretics in the fourth century, denominated from their founder Euſtathius, a monk ſo fooliſhly fond of his own profeſſion, that he condemned all other conditions of life. Whether this Euſtathius was the ſame with the biſhop of Sebaſté and chief of the Semiarians, it is not eaſy to determine.

He excluded married people from ſalvation; prohibited his followers from praying in their houſes, and obliged them to quit all they had as incompatible with the hopes of heaven.

He drew them out of the other aſſemblies of Chriſtians to hold ſecret ones with him, and made them wear a particular habit; he appointed them to faſt on Sundays; and taught them that the ordinary faſts of the church were needleſs, after they had attained to a certain degree of purity which he pretended to. He ſhewed great horror for chapels built in honour of martyrs, and the aſſemblies held therein.

Several women, ſeduced by his reaſons, forſook their huſbands, and abundance of ſlaves deſerted their maſters' houſes.

He was condemned at the council of Gangra, in Paphlagonia, held between the years 326 and 341. Socr. lib. ii. cap. 43 and Sozom. lib. iv. cap. 24. Hard. Concil. Coll. tom. i. p. 530.

EUSTATHIUS, in *Biography*, a ſaint in the Greek and Roman churches, and biſhop of Antioch, was tranſlated to that ſee from the biſhopric of Beræa, in Syria, about the year 323. He was a ſtrenuous opponent of the Arian doctrine, and is ſaid to have been the firſt eccleſiaſtic of conſequence who wrote againſt it. He was diſtinguiſhed by his zeal at the council of Nice in 325, and by his exertions in carrying the deciſions of that council into effect. This conduct ſo much exaſperated the Arian biſhops, that they got him accuſed of adhering to the doctrine of Sabellius, rather than to that of the council of Nice. His enemies alſo ſuborned an infamous woman to appear before the ſynod of the Eaſtern biſhops, to charge Euſtathius with being father of a child which ſhe held in her arms: other charges, equally diſreputable, were made againſt him: of theſe he was declared guilty, and depoſed from his paſtoral office. He was afterwards baniſhed to Trajanopolis in Thrace, where he died. Of his numerous writings we have few remains, excepting the fragments collected by Fabricius. Jerome thought highly of his talents; Sozomen commends him for his piety and eloquence, and ſays that his works were in high eſtimation in his time. By Theodoret he is called the great Euſtathius: but Socrates and others ſpeak very ſlightingly of his talents, and Socrates ſays he is one of thoſe obſcure perſons who had endeavoured to raiſe his own reputation by oppoſing Origen. He is generally admitted to have been the author of "A Diſſertation concerning the Ventriloquiſt or Pythoneſs," mentioned in Samuel, firſt book, chap. xxvii. written againſt Origen on that ſubject. This was publiſhed by Alladius in Greek, with a Latin verſion, in 1629, and may be found in the 29th volume of the "Bibliotheca Patrum," and in the eighth volume of the "Critici Sacri." Fabr. Bib. Græc. vol. viii. Cave's H. L. vol. i. Lardner's Works, vol. iv.

EUSTATIA, or Eustatius, *St.*, in *Geography*, one of the leeward Caribbee iſlands; which is a huge pyramidal rock riſing out of the ſea, about 29 miles in compaſs; but for its ſize the Dutch, by their induſtry, rendered it one of the moſt valuable of the Caribbees. The ſides of the mountains are laid out in pretty ſettlements; but they have neither ſprings nor rivers. Sugar and tobacco have been the chief produce of this iſland, which the Dutch have cultivated even to the top of the pyramid, which terminates in a plain ſurrounded with woods, having a hollow in the middle that ſerves as a den for wild beaſts. This iſland has afforded ſubſiſtence for five thouſand white people, and fifteen thouſand negroes, who rear hogs, kids, rabbits, and all kinds of poultry in ſuch abundance, that they have been able to ſupply even their neighbours. It has but one landing place, which the original occupiers, finding difficult of acceſs, fortified, ſo as to render it almoſt impregnable. Such for many years was the policy of the Dutch in the government of this iſland, that they have been jealous of admitting any ſtrangers into their harbour, and kept them ignorant of its internal riches, whilſt it has ſerved as a ſtorehouſe for all European commodities. The property of it was firſt granted by the States-General to certain merchants of Fluſhing. It was firſt ſettled about the year 1600; but in the wars between the Engliſh and Dutch in 1665, the latter were diſpoſſeſſed of it by an armament from Jamaica. The Engliſh were afterwards diſpoſſeſſed by the combined forces of the Dutch and French; and the latter kept poſſeſſion of it till it was reſtored to the Dutch by the treaty of Breda. Soon after the revolution, the French ejected the Dutch from this iſland, whence they were again driven by the Engliſh under ſir Timothy Thornhill, who, with a view to the protection of the Dutch, left a ſmall Engliſh garriſon in the fort. The peace of Ryſwick reſtored the Dutch to the entire poſſeſſion of the iſland. In the year 1781 this iſland was obliged to ſurrender to the Engliſh under admiral Rodney, who confiſcated the private property of the inhabitants under a plea that they had aſſiſted France and the United States with naval and other ſtores. Before the cloſe of the year it was retaken by the French under the command of the marquis de Bouille; but reſtored to the Dutch at the peace in 1783. It is diſtant 9 miles N. W. from St. Chriſtopher's. N. lat. 17° 30′. W. long. 63° 8′.

Eustatia, is alſo the name of a town in the fore-mentioned iſland.

EUSTATIUS, in *Biography*, archbiſhop of Theſſalonica, flouriſhed in the 12th century, under the emperors Manuel, Alexius, and Andronicus Comnenus. He is celebrated for his great learning as a grammarian and critic, and is eſpecially known as a commentator on Homer and Dionyſius the geographer. His annotations on the former are copious, and abound in hiſtorical and philological deſcriptions: they were publiſhed at Rome in four volumes folio, between the years 1542 and 1550, and have been re-printed, particularly at Florence in 1730, with the notes and tranſlations of Politi and Salvini. The commentaries on Dionyſius were firſt printed in the Greek, by Robert Stephens in 1547, and have been ſeveral times re-printed. A Latin verſion of them was given by Politi in 1742, at Geneva, in two volumes octavo. Moreri.

EUSTEPHIA, in *Botany*, ευϛεφιος, *wearing a beautiful crown*, alluding to the coronet formed in the mouth of the flower, by the tranſverſe ſegments of the ſtamens. Cavan. Ic. v. 3. 20. Willd. Sp. Pl. v. 2. 48. Vent. Regn. Veg. v. 2. 282. Claſs and order, *Hexandria Monogynia*. Nat. Ord. *Spathaceæ*, Linn. *Narciſſi*, Juſſ.

Gen. Ch. *Cal.* Sheath oblong, divided to the baſe into four acute ſegments, withering. *Cor.* ſuperior, of one petal, tubular, regular, in ſix deep, linear, obtuſe, nearly equal ſegments, three of which are internal; without any appendage at the mouth. Nectary ſix little cavities in the baſe or tube of the corolla. *Stam.* Filaments ſix, inſerted into the bottom of the corolla, juſt above each nectariferous pore, linear, flat, ſomewhat longer than the corolla, and three-cleft juſt where they emerge from it, the middle ſegment longeſt, erect, ſlender, bearing the anther, the lateral ones ſhort, and horizontally divaricated, forming a crown in the mouth of the corolla; anthers incumbent, ovate. *Piſt.* Germen inferior, turbinate, triangular; ſtyle thread-ſhaped, the length of the ſtamens; ſtigma ſwelling, undivided. *Peric.* as far as can be judged from the germen, a capſule of three cells. *Seeds* . . . .

Eſſ. Ch. Calyx a divided ſheath. Corolla ſuperior, regular, tubular, cylindrical, in ſix deep ſegments. Nectary ſix pores in the baſe of the corolla. Filaments with two lateral points.

1. E. *coccinea*, Cavan. Ic. t. 238. Flowered in the royal garden at Madrid in May 1794, but its native country is unknown. *Root* perennial, bulbous. *Leaves* radical, ſeveral, linear, obtuſe, ſomewhat falcated. *Stalk* ſolitary, above a foot high, ſtout, ſmooth, ſlightly compreſſed. *Flowers* four in a terminal umbel, drooping, ſcarlet, reſembling thoſe of *Cyrtanthus anguſtifolius*, but very diſtinct in their ſtructure. *Sheath* nearly as long as the partial flower-ſtalks and flowers together.

EUSTOCHIUM, or Eustochia, in *Biography*, a Roman lady in the 4th century, who is highly ſpoken of by St. Jerome, was a deſcendant from the families of the Scipios and Paulus Æmilius, and rendered herſelf celebrated for the proficiency which ſhe had made in literature. She was well acquainted with the Hebrew and Greek, as well as the Latin tongues, and converſant with the moſt important theological ſubjects. In the Catholic world her memory is cheriſhed on account of her early devotedneſs to a religious courſe. She profeſſed herſelf a diſciple of St. Jerome, whom ſhe followed from Rome to Cyprus, and thence to Antioch, Egypt, and numerous other places, and at length fixed her reſidence in a monaſtery at Bethlehem. Her mother Paula deſerted a young family to accompany her in theſe excurſions. Moreri.

EUSTRATIUS, a preſbyter of the church of Conſtantinople, flouriſhed about the year 578, and was author of "A Treatiſe concerning the Souls of the Dead," intended to prove that the ſouls of all men are active after their ſeparation from the body, and that they act differently according to the difference of their merits. He was author alſo of "The Life of the Patriarch Eutychius," which appears to have been a funeral oration pronounced by Euſtratius in the great church at Conſtantinople, a ſhort time after the death of the ſubject of it.

Eustratius, archbiſhop of Nice in the twelfth century, is mentioned by Anna Comnena, and other Latin writers, as a perſon of profound learning and ſkill, as well in civil as eccleſiaſtical affairs. He was author of "A Treatiſe againſt Chryſolanus concerning the proceſſion of the

Holy Spirit," and of other unpubliſhed treatiſes. The only works of his which have been committed to the preſs are "Commentaries on the latter Analyſis of Ariſtotle," publiſhed in Greek at Venice, in 1534: and "Commentaries on the Ethics of Ariſtotle," publiſhed likewiſe in Greek at the ſame place, 1536, and at Paris in Latin, 1543. Moreri.

EUSTYLE, formed of ευ, *bene*, *well*, and ϛυλος, *column*, in *Architecture*, a kind of edifice, where the columns are placed at a moſt convenient diſtance one from another, the intercolumniations being all juſt two diameters and a quarter of the column, except thoſe in the middle of the fronts, before and behind, which are three diameters diſtant.

The euſtyle is a medium between the pycnoſtyle, and areoſtyle.

Vitruvius, lib. iii. cap. 2 obſerves, that the euſtyle is the moſt approved of all the manners of intercolumniation, and that it ſurpaſſes all the reſt in conveniency, beauty, and ſtrength.

EUTACA, in *Geography*, a mountain of Egypt, near the Red ſea; 12 miles S. of Suez.

EUTAM, a ſmall iſland of the Weſt Indies, near the eaſt coaſt of Porto-Rico. N. lat. 18° 18'. W. long. 64° 41'.

EUTERPE, in *Botany*, ευτερπης, *pleaſing or agreeable.* Gærtn. v. 1. 24. t. 9. Juſſ. 453. Suppoſed by Juſſieu to be the ſame with his *Corypha Sabal*, ſee our CORYPHA, ſp. 3, which Adanſon likewiſe made a diſtinct genus. If it be ſo, Gærtner's claſſical appellation may well take place of the barbarous Sabal.

EUTERPE, of ευ, *well*, and τερπω, *I delight*, in *Mythology*, one of the nine Muſes, which preſided over wind-inſtruments: ſhe is repreſented with a crown of flowers, playing on a double flute, with Cupid at her knees. Sometimes ſhe has a maſk in her left hand, and a club in her right. To her the invention of tragedy is aſcribed.

EUTHIA, a term in the *Ancient Muſic*, which implies a ſucceſſion of notes proceeding from grave to acute. Euthia was one of the parts of the ancient Melopœia.

EUTHYMIA, Ευθυμια, among the Greeks, ſignified ſuch a diſpoſition or ſtate of the mind, as could not be ruffled either by good or bad fortune, by ſickneſs or health, good or evil. Mem. Acad. Inſcript. vol. xiv. p. 131.

EUTHYMIUS, in *Biography*, flouriſhed in the tenth century, firſt as a monk, and afterwards, by his talents and virtues, he ſo far recommended himſelf to notice, that he obtained the appointment of "Syncelle," an office of high rank under the patriarch, and he was alſo choſen confeſſor by the emperor Leo VI. In 906 the patriarch Nicholas was depoſed by the emperor, and Euthymius was elevated to it in his ſtead. Upon the death of Leo, his ſucceſſor Alexander II. re-eſtabliſhed Nicholas in the patriarchal chair, and ſentenced Euthymius to baniſhment, a puniſhment which he bore with fortitude and patience till his death, in or about the year 920. Another patriarch of Conſtantinople, of the name of Euthymius, obtained that dignity in the year 1410, and enjoyed it till his death in 1416. Moreri.

EUTHYMIUS ZIGABENUS, was a monk of the order of St. Baſil, who flouriſhed at Conſtantinople about the beginning of the twelfth century. By his ſuperior talents he acquired the patronage and eſteem of the emperor Alexius Comnenus, at whoſe command he drew up his Panoplia, or defence of the orthodox faith againſt all hereſies. It conſiſts chiefly of paſſages ſelected from the writings of the ancient Greek fathers on different points, in which heretics have departed from the Catholic doctrine. Euthymius was alſo the author of "A Commentary upon the Pſalms and Canticles," of which a Latin verſion was publiſhed by Saulius in 1530, and ſince that time more than once reprinted: "A Commentary on the four Evangeliſts," ſelected from the ancient fathers; "Commentaries on the Epiſtles of St. Paul;" "A Treatiſe againſt the Hereſies of the Maſſalians, &c." Moreri.

EUTHYPOROS, from ευθυς, *ſtraight*, and ποριζω, *to paſs into*, among the old terms of *Surgery*, meant extenſion, made in a ſtraight line, in order to reduce fractures, and diſlocation.

EUTIN, in *Geography*, a town of Germany, in the biſhopric of Lubeck, ſituated by the ſide of a lake, the uſual reſidence of the prince biſhop, the biſhopric, like that of Oſnaburg, being ſecular; 20 miles N. of Lubeck. N. lat. 54° 10'. E. long. 10° 32'.

EUTOCIUS, in *Biography*, a conſiderable mathematician, who lived at the time of the decline of the ſciences in Greece, was a native of Aſcalon, in Paleſtine, and a diſciple of Iſidorus, one of the celebrated architects employed by the emperor Juſtinian. He probably flouriſhed about the commencement of the ſixth century, though we have no particulars reſpecting his life; but his works reflect much honour on his memory. He wrote elaborate and perſpicuous "Commentaries on the books of Archimedes concerning the Sphere and Cylinder;" and alſo on the firſt four books of the Conics of Apollonius Pergæus. Theſe commentaries have not only elucidated many difficult paſſages in thoſe profound writers, but have tended to throw light on the hiſtory of mathematics. There have been many editions of them, but the moſt magnificent was that in the edition of the works of Archimedes, printed at Oxford in folio, in the year 1792, which was prepared for the preſs by Torelli of Verona; and that in Dr. Halley's edition of the eight books of Apollonius, publiſhed at Oxford in 1710. Moreri. Montucla.

EUTROPIUS, a Latin hiſtorian of the fourth century, is ſuppoſed to have been a native of Acquitain. He bore arms under Julian, in his expedition againſt the Perſians, and is ſaid to have riſen to the ſenatorian rank. He wrote ſeveral works, of which the only one remaining is an abridgment of the Roman hiſtory, in ten books, from the foundation of the city to the reign of the emperor Valens. This is a neat compendium, and has long ſince been received as a ſchool-book. Moreri.

EUTROPIUS, the eunuch miniſter of the emperor Arcadius, who roſe by baſe and infamous practices from the vileſt condition to the higheſt pitch of opulence and power, was probably a native of Aſia. In the year 395 he was made great-chamberlain to Arcadius, emperor of the Eaſt. After the fall of Rufinus, he ſucceeded that miniſter in the confidence of his maſter, and roſe to unlimited authority. All perſons of whatever rank humbled themſelves before the favourite, who became the capricious diſpoſer of honours and emoluments of every kind, and in 399 he, an eunuch, even aſſumed the dignity of conſul, a diſgrace to Rome never before equalled. Honours, if ſuch they may be denominated, of every kind were accumulated upon him: the towns were filled with his ſtatues, and he was entitled the third founder of Conſtantinople. His predominant paſſion was the love of money, and of courſe the moſt ſhameful venality directed all appointments to the high offices of the ſtate. As a ſecurity to his perſon, a law of treaſon was paſſed, which extended the penalties of that crime to every attempt againſt the miniſters and ſervants, as well as againſt the perſon of the emperor. Such a ſhield was not ſufficient to defend him from the influence of court intrigue. An inſult

ſult which he offered to the empreſs cauſed her to implore the protection of her huſband, and at the ſame moment complaints were offered againſt him from other quarters, which induced the emperor to ſign his condemnation, and the fallen and juſtly execrated favourite was obliged to ſeek refuge in the ſanctuary of a church, from the pulpit of which Chryſoſtom pronounced an eloquent diſcourſe, pointing him out to the people as an example of the inſtability of human grandeur. He afterwards ſurrendered himſelf on promiſe that his life ſhould be ſpared, and was condemned to perpetual exile in Cyprus. Thither he was conveyed, but being haſtily brought back and tried on another charge, he was condemned and beheaded in the year 399. Gibbon.

EUTYCHIA, in *Ancient Geography*, an iſland of the Ægean ſea, before the Pagaſei gulf.

EUTYCHIANS, in *Eccleſiaſtical Hiſtory*, ancient heretics, who denied the duplicity of natures in Chriſt; thus denominated from Eutyches, the archimandrite, or abbot of a monaſtery at Conſtantinople, who began to propagate his opinion A. D. 448.

The averſion Eutyches bore to the hereſy of Neſtorius threw him into another extreme not leſs dangerous than that he ſo warmly oppoſed; though ſome paſſages in St. Cyril, which raiſed the unity of the perſon of Jeſus Chriſt very high, contributed likewiſe to his deluſion. At firſt he held that the *Logos*, *Word*, brought his body down with him from heaven; which was a near approach to the hereſy of Apollinarius; and, though he afterwards teſtified the contrary, in a ſynod at Conſtantinople, wherein he was condemned, yet he could not be brought to acknowledge that the body of Jeſus Chriſt was conſubſtantial with ours.

In effect, he did not ſeem quite ſteady and conſiſtent in his ſentiments; for he appeared to allow of two natures, even before the union; which was apparently a conſequence he drew from the principles of the Platonic philoſophy, which ſuppoſes a pre-exiſtence of ſouls; accordingly he believed that the ſoul of Jeſus Chriſt had been united to the divinity, before the incarnation; but then he allowed no diſtinction of natures in Jeſus Chriſt ſince his incarnation.

See the diſſertation of H. Hardouin, "De Sacramento Altaris;" wherein that Jeſuit endeavours to unfold all the ſentiments of the Eutychians.

This hereſy was firſt condemned in a ſynod held at Conſtantinople, by Flavian, in 448, approved by the council of Epheſus, called *Conventus latronum*, in 449, and re-examined and fulminated, in the general council of Chalcedon, in 451. The legates of pope Leo, who aſſiſted at it, maintained, that it was not enough to define, that there were two natures in Jeſus Chriſt, but inſiſted ſtrenuouſly, that, to remove all equivocations, they muſt add theſe terms, *without being changed, or confounded, or divided.*

The hereſy of the Eutychians, which made a very great progreſs throughout the Eaſt, at length became divided into ſeveral branches. Nicephorus makes mention of no fewer than twelve; ſome called *ſchematici*, or *apparentes*, as only attributing to Jeſus Chriſt, a phantom, or appearance of fleſh; and no real fleſh; others *Theodoſians*, from Theodoſius, biſhop of Alexandria; others *Jacobites*, from one James, *Jacobus*, of Syria; which branch eſtabliſhed itſelf principally in Armenia, where it ſtill ſubſiſts. Others were called *Acephali*, q. d. *without head;* and *Severians*, from a monk called Severus, who ſeized on the ſee of Antioch in 513.

Theſe laſt were ſubdivided into five factions, *viz. Agnoetæ*, who attributed ſome ignorance to Jeſus Chriſt; the followers of Paul; Μελαινοι, that is, the *black Angelites*, thus called from the place where they were aſſembled; laſtly, *Adrites*, and *Cononites.*

Eutychians was alſo the name of another ſect, half Arian, half Eunomian, which aroſe at Conſtantinople in the fourth century.

It being then a matter of mighty controverſy among the Eunomians at Conſtantinople, whether or no the Son of God knew the laſt day and hour of the world, particularly with regard to that paſſage in the Goſpel of St. Matthew, chap. xxiv. ver. 36. or, rather, that in St. Mark, xiii. 32. where it is expreſſed, that *the Son did not know it, but the Father only;* Eutychius made no ſcruple to maintain, even in writing, that the Son did not know it; which ſentiment diſpleaſing the leaders of the Eunomian party, he ſeparated from them, and made a journey to Eunomius, who was then in exile.

That heretic acquieſced fully in Eutychius's doctrine, and admitted him to his communion; Eunomius dying ſoon after, the chief of the Eunomians at Conſtantinople refuſed to admit Eutychius; who, upon this, formed a particular ſect of ſuch as adhered to him, called *Eutychians.*

This ſame Eutychius, and one Theophronius, as was ſaid in Sozomen's time, were the occaſions of all the changes made by the Eunomians in the adminiſtration of baptiſm; which conſiſted, according to Nicephorus, in only uſing one immerſion, and not doing it in the name of the Trinity, but in memory of the death of Jeſus Chriſt.

Nicephorus calls the chief of that ſect not Eutychius, but Eupſychius, and his followers Eunomioeupſychians.

EUTYCHIANUS, in *Biography*, biſhop of Rome, ſucceeded to that high office on the death of Felix, in the year 275, and preſided over the church about eight or nine years, when he died. Catholics have conſidered him as a martyr to the cauſe of truth; but hiſtorians, in general, infer, from the unmoleſted ſtate of Chriſtians, at that period, in Rome, that he died a natural death. There are two decretal epiſtles of this pope extant, relative to ſubjects of eccleſiaſtical diſcipline. Moreri. Bower.

EUTYCHIUS, patriarch of Conſtantinople, was born in the year 512. He was brought up to the eccleſiaſtical profeſſion, and obtained in early life the epiſcopal dignity in a town of Pontus, which he afterwards relinquiſhed, and entered into a monaſtery in the city of Amaſæa. In 552 he was deputed by the biſhop of that city to Conſtantinople, as his repreſentative, in the approaching general council that was to be held there. Before the meeting of the council, he obtained the favour of Juſtinian, who raiſed him to the patriarchate of Conſtantinople, which became vacant in the year 553, by the death of Mennas. Almoſt immediately after he had aſſumed the new character, he preſided at the council in which the opinions of Origen and his followers were condemned. Some years after, *viz.* in the year 564, Juſtinian endeavoured to obtain the patriarch's ſanction to a doctrine which he had adopted, *viz.* that the body of Jeſus Chriſt was rendered incorruptible before his reſurrection, by the union of the divine and human natures; but when Eutychius ſteadily refuſed to countenance the opinion, the emperor depoſed him from the patriarchate and ſent him into exile. In 578, he was reinſtated in the ſee of Conſtantinople, by the emperor Tiberius II. and he died in the year 585, at the age of 73. There is extant, in the fifth volume of the "Collectio Conciliorum," an epiſtle of his to pope Vigilius.

He was author of other pieces; of theſe a fragment of one only remains, "Concerning the Souls of the Dead." Moreri.

EUXINE Sea, called the *Black Sea*, as it is ſaid, either from its black rocks, or dangerous navigation, an inland ſea, ſituated partly in Europe, and partly in Aſia; bounded on the north by the government of Caucaſus and Ekatarinoſlaf, on the caſt by Mingrelia and Georgia, on the ſouth by Natolia, and on the weſt by European Turkey. This ſea is divided into the Euxine proper, the Pontus Euxinus, computed to be 1000 verſts in length, and 500 in breadth, and the ſea of Azof, (ſee Azof) the Palus Mæotides of the ancients, which, without including the bay of Tagauroh, is ſtated to be 200 verſts long, and 160 verſts broad. Both theſe are now entirely within the confines of the Ruſſian empire. The ſea of Azof, called palus, or a marſh, by the ancients, becauſe it was polluted by mud, is united to the Euxine by the ſtraits of Caſſa, or the ancient Cimmerian Boſphorus. The moſt important of the bays formed by theſe ſeas are the Liman, at the mouth of the Dnieper, the bay near Perekop, and that cloſe to Yenikalé. The moſt conſiderable iſland belonging to theſe ſeas in the vicinity of the Ruſſian coaſts, is Taman. The principal harbours are Caffa, now Theodoſia, Sebaſtopol, Koſlof, Balaklava, and ſome others. At the weſtern extremity of theſe ſeas, within the province of Taurida, is a very large pool, called Sivaſh, or the Putrid ſea, which is about 140 verſts long, and 54 broad. The chief rivers that fall into the Euxine, are the Kuban, or Hypanis of the ancients, the Don, or ancient Tanais, the Dnieper or Boryſthenes of ancient geographers, and the Bogur, which riſes in Poland, parting that kingdom, and a portion of European Turkey from Ruſſia, and at Otchakof, falls into the Euxine. The Euxine ſea was formerly denominated αξινος, or *inhoſpitable*, on account of the barbarity of the inhabitants of its coaſts; but when they became civilized by their commerce with the Greeks, the name was changed into ευξινος, i. e. *hoſpitable*, or favourable to ſtrangers.

EUZET, a town of France, in the department of the Gard; nine miles W. N. W. of Uzes.

EUZOIUS, in *Biography*, was in early life a deacon of the church of Alexandria, from which office he was expelled by Alexander, biſhop of that ſee, at the ſame time with Arius, on account of his eſpouſing the principles of that celebrated character. They were both involved in the like condemnation at the council of Nice. About the year 355, he preſented a confeſſion of faith to the emperor Conſtantine, which met with the approbation of that ſovereign, and which was the means of bringing him into conſequence at the imperial court, when the orthodox party were thrown in the back ground. He was appointed to the ſee of Antioch, and called upon to baptiſe the emperor Conſtantius. His influence was now very conſiderable, and to this the friends of Athanaſius attribute much of the perſecution by which that biſhop was harraſſed. Moreri.

Euzoius, biſhop of Cæſarea, was educated in that city at the ſame time with Gregory Nazianzen. On the death of Acacius he obtained the biſhopric of Cæſarea, after maintaining a violent conteſt with the different rival candidates. He was in principle an Arian, or nearly ſo, and on that account was depoſed from his ſee under the reign of the emperor Theodoſius, about the year 380. He was author of numerous treatiſes now loſt; poſſeſſed with much learning, and was very diligent in the diſcharge of his epiſcopal functions; but he is principally celebrated on account of his great exertions in promoting the intereſts of ſcience and literature. He manifeſted much zeal in the reſtoration and improvement of the library at Cæſarea, which had been originally collected by Origen and Pamphilus, and was at this period fallen into decay. To this object he devoted his time and labour, taking care that faithful tranſcripts ſhould be procured of ſuch books as were in a periſhing ſtate, and increaſing their numbers by new collections. Moreri.

EWAGE, *Ewagium*, in our *Old Writers*, the ſame with *aquage*, which is toll paid for water-paſſage. It is derived from the French *eau*, water.

EWALD, John, in *Biography*, a Daniſh poet, was born at Copenhagen in the year 1743. His father was a clergyman, and when he found his own end approaching he ſent his ſon for education to Sleſwick, and died in a few hours after. Licht, the perſon to whoſe care young Ewald was entruſted, treated him in every reſpect as his own ſon, and gave him free acceſs to his library. The books moſt agreeable to his taſte were romances, which he read with the greateſt avidity. The adventures of Tom Jones and Robinſon Cruſoe, particularly the latter, had made ſuch an impreſſion on his mind, and had excited his paſſions ſo ſtrongly, that he eloped from Sleſwick in his thirteenth year, in order to proceed to Holland, that he might undertake a voyage to Batavia, in the hope of being ſhipwrecked and thrown on ſome deſert iſland. Scarcely had he travelled four miles, before he was overtaken by his preceptor and friend, who carried him back by force. At another time having read and heard of many romantic tales reſpecting ſaints and martyrs, he was deſirous of becoming a martyr for the cauſe of Chriſtianity. At length he reſolved upon the profeſſion of a ſoldier, which being oppoſed by his friends, he left home, in company with his brother, and joined the Pruſſian ſervice, from this he deſerted to the Auſtrian army, in which he was firſt a drummer, and then a ſerjeant. A commiſſion was offered him, provided he would embrace the Catholic religion, which he abſolutely refuſed, and in a ſhort time deſerted again. On his return to Denmark he devoted himſelf to theology, and ſtudied with ſo much deligence as to be fit for examination in the courſe of a year. He had paid his addreſſes to a lady, who, ſuſpecting him not to be in earneſt, gave her hand to another: this ſo affected Ewald as to produce a complete change in his diſpoſition, and to give his ideas a melancholy caſt. He now abandoned himſelf to pleaſure, and injured his conſtitution. To give vent to the effuſions of his mind, he wrote a piece, called "The Temple of Good Fortune," which proved the ſource of all his future fame. It obtained the approbation of the ſociety of Belles-lettres; and procured him the friendſhip of M. Carſtens, a zealous votary of the muſes, which he enjoyed, without interruption, during the remainder of his life. On the death of Frederic V. in 1766, he compoſed an elegy, which was received with univerſal approbation, and Ewald, intoxicated with the praiſes beſtowed upon his work, began to conſider himſelf one of the greateſt poets that Denmark had ever produced. The ſociety of Belles-lettres propoſed as the ſubject of a prize the beſt ode on any of the attributes of the deity, and Ewald, determined to try his fortune, made choice of the divine goodneſs, and had already formed his plan, when he learned that Benzon, one of his moſt intimate friends, was employed on the ſame ſubject. Unwilling to enter the conteſt with a friend he abandoned his ſubject, and wrote his Adam and Eve, a ſort of half drama, in one act, which poſſeſſed much merit, but without order or any regard to the laws of compoſition. He hoped that this might obtain the prize, but was diſappointed, and began to ſtudy poetry, being now reſolved to read; and not to write any more for two years. The works of Corneille and Klopſtock fell into his hands, and gave his taſte a new direction. His next work was "Rolfe Krage," a tragedy in the ſtyle of Oſſian, and "The ſongs of Skalden," which he wrote under the eye of Klopſtock, who had a very great and ſincere affection for him. During the time he was employed on this piece, he was attacked by a diſeaſe, under which he languiſhed for ten years. It proceeded from the gout, and was often attended with excruciating pain, yet his ſpirits and cheerfulneſs rarely forſook him, and he wrote in the intervals of his eaſe ſome ſmall theatrical pieces, which in part related to preſent times and manners, and which abounded with humour and the keeneſt ſatire. Ewald had obtained from the king a penſion of a hundred dollars, but this being inſufficient for his maintenance, he was obliged, by writing temporary poems, to gain a part of his livelihood, till the profits ariſing from the repreſentation of his theatrical pieces, and from the ſale of his works, ſhould place him beyond the fear of want. He died at Copenhagen in March 1781, in the thirty-eighth year of his age. In ſtrength of imagination, ſpirit and originality, Ewald ſurpaſſes all the other Daniſh poets. His excellent qualities gained him the affection of thoſe who knew him. He never proſtituted his muſe to improper purpoſes, and never, ſays his biographer, did an immoral or pernicious line flow from his pen. A complete edition of his works was publiſhed at Copenhagen between the year 1781—1791. Gen. Biog.

EWANICZOW, in *Geography*, a town of Poland, in the palatinate of Kaminiec; 64 miles N.N.W. of Kaminiec.

EWANO, a town of Poland, in Galicia; 36 miles S.E. of Halicz.

EWE, a ſmall iſland on the W. coaſt of Scotland, at the entrance of Loch Ewe. N. lat. 57° 53′. W. long. 5° 37′.

Ewe, in *Rural Economy*, the female of the ſheep kind of animals. It is of very great importance in the forming of this ſort of ſtock to have good ewes. (See Sheep.) It is the practice in ſome of the more northern diſtricts to have recourſe to the milking of the ewes in order to make cheeſe from it. But it is ſaid to have been lately found ſo injurious to the animals, and to be attended with ſo little profit, that it is, at preſent, much on the decline.

Ewe-*Cheeſe*, is that ſort of cheeſe which is prepared from the milk of the ewe. It is a very ſtrong pungent kind of cheeſe, which is not well reliſhed by many. Some, however, conſider it as very rich and excellent, preferring it to the other ſorts of cheeſe. In ſome places theſe cheeſes are made of a conſiderable ſize, perhaps, nearly as large as thoſe of the Cheſhire dairies, one, two, or three hundred ewes being milked regularly for the purpoſe. See Cheese.

EWELL, in *Geography*, is a market town in the hundred of Copthorne, and county of Surry, ſituated at the foot of Banſtead downs, diſtant S.E. by E. of London 13 miles. The weekly market is held on Thurſdays, and it has two annual fairs, one the 12th of May, the other the 29th of October. The number of houſes, according to the returns in 1801, is 194, and of inhabitants 1112. Here is the head of an extraordinary ſpring, which forms a curious natural jet d'eau, breaking out in ſeveral places. After watering Epſom-court meadows it flows in a fine ſtream called the Malden, and falls into the river Thames at Kingſton.

Near this town ſtood the magnificent palace, from its grandeur and ſplendid decorations, denominated "None-Such," erected by king Henry the Eighth. Charles the Second having conferred it upon his favourite miſtreſs, the infamous ducheſs of Cleveland, ſhe cauſed it to be taken down, and ſold the materials.

EWENNY, a river which has its ſource in the mountains to the north of Peterſton ſuper montem, and paſſing by Coychurch and Ewenny priory, joins the river Ogmore near Merthyr Mawr, below which it falls into the Briſtol channel. A phenomenon on this ſtream has given riſe to a geological error, which has generally been credited without proper inveſtigation, that the river makes a "dip under a mountain, appearing again near Nevern bridge, after a ſubterraneous paſſage of two miles." "Mr. Lethieuller obſerves, "that between Merthyr Mawr, near which alſo were deep ſands, and New-inn bridge, the river Ogmore, or rather a branch of it, runs a quarter of a mile under the hill, paſſing alſo under ſeveral natural bridges; after which, iſſuing out with great violence, it joins the main ſtream. The maps again here miſtake in giving this river the name of Ogmore before its junction with the Ewenny, after which only it aſſumes that name, being called before the Bridgend river, as it comes from Bridgend, where it runs under ground a little to the north of that place, and appears again from under Ogmore hill." See Archæologia, vol. iv. p. 27. It occurs near the junction of the Ewenny with the river Ogmore. From the foot of a long ridge of down, where the hill makes a bold eſcarpement to the vale, iſſues a large body of water, exceeding the quantity previouſly flowing down the river, except after rains. In its paſſage from under the hill it is heard to boil and rage, and ruſhes out with foaming impetuoſity, as though it had met with violent interruption in its courſe; and forms two ſtreams, which immediately appear different in the velocity of their motions and quality of their contents; one being what is vulgarly called *hard*, and the other *ſoft* water. The ſtream to the ſouthward is ſought for culinary, and that to the northward for lavatory purpoſes. In trying it, Mr. Evans obſerves, "the water from the oppoſite ſides of the ſtream had a different effect upon the tongue and palate, and by a brief analyſis it was diſcovered, that the one contained a portion of calcareous matter in ſolution; and the other left but little reſidue, which was of an argillaceous nature." An attempt was then made to aſcertain whether the river might not enter ſome other part of the hill, and by a ſubterraneous paſſage here ſeek daylight again, as is reported of the Deveril in Wiltſhire, and the Mole in Surry. But after a fruitleſs ſearch the ſmalleſt veſtige of ſuch a ſubterraneous courſe could not be traced. The phenomenon therefore in queſtion appears to proceed from two powerful ſprings, riſing in the internal parts of the hill, the ſtreams of which having flowed ſeparately, here unite, but without intermingling their waters, till they join the Ewenny. Evans's Tour in South Wales.

Ewenny *Priory*, in *Antiquity*, was a monaſtery of the Benedictine order, founded by John Maurice de Lundres, Lord of Ogmore, A. D. 1140; and given as a cell to Glouceſter Abbey. Its revenues, as valued at the diſſolution, were 78*l.* 0*s.* 8*d.* It ſtands cloſe to the road leading from Newton to Pyle in Glamorganſhire, South Wales, in a marſhy plain, near the banks of the river Ewenny. It was ſurrounded by ſtrong embattled walls, having two gateways; and the one forming the principal entrance had two portculliſes: theſe, with parts of maſſive towers viſible among its ruins, indicate it was intended as a place of ſecurity, as well as religious retirement. The buildings appear to have been very extenſive, and ſome rooms, which formed the abbot's lodge yet remaining, are large and ſtately; particularly the great hall or refectory. But the abbey church, ſtill ſtanding, is a noble edifice, the ſimple and uniform architecture of which muſt be gratifying to every admirer of the arts. It is a maſſive building of a cruciform ſhape, conſiſting

ing of a nave, two tranſepts, and a choir; in which heavy circular arches reſt upon round bulky columns with ſimple capitals: the windows alſo and door-ways have all the circular arch, which have induced ſome to refer it to a Saxon period. The whole certainly denotes the earlieſt Norman ſtyle of architecture. The curious ſtone vaulted groined roof of the choir claims particular attention; and the neglected effigies of the founder, bearing this inſcription, "Ici giſt Morice de Lundres le fundur, Deu li rende ſun labur. Am." In the ſouth tranſept lies another rude ſtone figure of a knight in armour, which has generally been thought commemorative of Pain de Tuberville lord of Coity. But ſir Richard Hoare has ſhewn this ſtatement, which originated with Camden, to be erroneous. After having the tomb cleaned, he was enabled to read the inſcription thus,

> "Sire Roger de Remi giſt ici
> Deu de ſon alme eit merci am."

The perſon here named "De Remi," ſir Richard ſuppoſes to have been ſome friend, and follower of Morice de Lundres. The floor of the church has been paved with glazed porcelain tiles, ornamented with various devices, ſuch as are ſeen in other buildings of a ſimilar nature; but few now remain. The nave is at preſent uſed as the pariſh church for divine worſhip, and the choir has a cemetery for diſtinguiſhed families in the vicinity: monuments for whom, particularly that of Carne, adorn its walls. It muſt be matter of regret to thoſe intereſted in ancient buildings, to ſee the preſent dilapidated ſtate of this once noble ſtructure: in many places rooflefs, the windows unglazed, the roof of the choir cracked, the ſepulchral monuments broken, and thrown careleſsly about; and this noble ſanctuary, which has ſtood near ſeven hundred years, and exhibits the moſt perfect ſpecimen of early Norman architecture of any church in the kingdom, rapidly approaching to its diſſolution. Evans's Tour in South Wales, and the Tranſlation of Gyraldus's Itinerarium by ſir Richard Colt Hoare.

EWER, in *Rural Economy*, a term ſometimes provincially applied to the udder of the cow, or other animal. See Udder

EWES, or Eus, in *Geography*, a river of Scotland, which joins the Eſk at Langholm, in Dumfries-ſhire; and the valley through which it paſſes is called Ewesdale.

EWRY, an office in the king's houſhold, where they take care of the linen for the king's table; lay the cloth, and ſerve up water in ſilver ewers after dinner, whence the office takes its name.

EXACERBATION, in *Medicine*, ſignifies the increaſe or return of the ſymptoms in thoſe fevers of the remittent, intermittent, or even continued claſs, in which the febrile condition is renewed at regular periods, or becomes augmented. It is nearly ſynonymous with *Paroxyſm*; but is more particularly reſtricted to the periodical increaſe of the remittent, or continued fevers, in which there is no abſolute ceſſation of the febrile ſtate. The evening exacerbation of hectic fever is a familiar example. Dr. Cullen aſſerts his belief, that there are commonly two exacerbations and remiſſions both of hectic and of continued fever in the day; the one in the forenoon, the other in the evening: that of the morning, however, if it really occurs, is leſs diſtinct, and many practitioners have been unable to detect it. See Fever, and Hectic.

EXACHORD. See Hexachord.

EXACHORDE, *Fr.* Essacordo, *Ital.*, an inſtrument with ſix ſtrings, or a ſyſtem compoſed of ſix ſounds, ſuch as the hexachord of Guido, which ſee.

EXACTION, in *Law*, a wrong done by an officer, or one pretending to have authority: in taking a reward, or fee, for that in which the law allows not of any.

The difference between exaction and extortion, conſiſts in this; that extortion is, where the officer takes more than his due; and exaction, where he wreſts a fee, or reward, where none is due.

EXACTIS, in *Natural Hiſtory*, a name given by Linkius, and ſome other authors, to a ſpecies of ſtar-fiſh, of the more branched kind, whoſe rays are ſix in number, when they firſt part from the body, but very ſoon branch out into a great number more. See Star-*fiſh*.

EXACTOR Regis, in *Law*, the king's exactor, or collector. Sometimes it is taken for the ſheriff. But generally, "quicunque publicas pecunias, tributa, vectigalia & res fiſco debitas exigit, proprie nominatur exactor regis."

EXACUM, in *Botany*, a name which Pliny ſays has been given to the Leſſer Centaury, becauſe it carries off all bad medicines by ſtool, apparently from ἐξ, *out of*, and [illegible], *to drive*, or *force onward*. Linn. Gen. 57. Schreb. 77. Willd. Sp. Pl. v. 1. 634. Sm. Fl. Brit. 182. Mart. Mill. Dict. v. 2. Juſſ. 142 Gærtn. t. 114. Claſs and order, *Tetrandria Monogynia*. Nat. Ord. *Rotaceæ*, Linn. *Gentianæ*, Juſſ.

Gen. Ch. *Cal.* Perianth inferior, in four deep, ovate, ſlightly ſpreading, permanent ſegments. *Cor.* of one petal, permanent, ſalver-ſhaped; tube inflated, the length of the calyx; limb in four deep, roundiſh, ſpreading lobes. *Stam.* Filaments four, thread-ſhaped, inſerted into the tube, not ſo long as the limb; anthers roundiſh. *Piſt.* Germen ſuperior, oval, filling the tube; ſtyle thread-ſhaped, rather oblique, the length of the ſtamens; ſtigma capitate. *Peric.* Capſule elliptical, as long as the calyx, compreſſed, with a longitudinal furrow at each ſide, of two cells, burſting at the top. *Seeds* numerous, ſmall, roundiſh, affixed to a central receptacle which forms the partition of the capſule.

Eſſ. Ch. Calyx in four ſegments. Corolla ſalver-ſhaped, with an inflated tube. Capſule ſuperior, with two furrows, two cells, and many ſeeds, burſting at the top. Stigma capitate.

Obſ. The flowers in ſome ſpecies are five-cleft, with a correſpondent number of ſtamens.

Since this genus was founded by Linnæus on the examination of ſome dried Eaſt Indian ſpecimens of his *E. ſeſſile* and *pedunculatum*, Sp. Pl. 163, ſeveral ſpecies have been added to it by different botaniſts, either entire new diſcoveries, or ſeparated from the old genus of *Gentiana*. Vahl has alſo referred hither the *Coutoubea* of Aublet, Guian. t. 27, 28, with unqueſtionable propriety, though Juſſieu and Schreber have kept it ſeparate, the latter by the name of *Picrium*, alluding to its bitterneſs.

Our only Britiſh ſpecies is *E. filiforme*, Engl. Bot. t. 235, found in ſpongy or ſandy bogs, in Dorſetſhire, Devonſhire, and Cornwall, flowering in July. This is a ſmall, ſlender, inconſpicuous annual, with a branched *ſtem*; oppoſite, ſeſſile, lanceolate *leaves*; and ſmall, terminal, ſolitary, yellow *flowers*, expanded only while the ſun ſhines bright upon them. It was the *Gentiana filiformis* of Linnæus and all following authors, till referred to *Exacum* in Engl. Bot.

E. *viſcoſum*. Sm. Ic. Pict. t. 18. (Gentiana viſcoſa; Ait. Hort. Kew. v. 1. 321.) has pentandrous five-cleft flowers. This is a handſome green-houſe plant, brought from the Canary iſlands by Mr. Maſſon. The *ſtem* is ſhrubby, three feet high, with oblong ribbed *leaves*, and large terminal panicles of yellow *flowers*.

The annual ſpecies are ſcarcely to be cultivated, no ſucceſsful method of raiſing them from ſeed in a garden having yet been diſcovered.

EXÆRESIS, from εξ, *out of*, and αιρω, *to remove*, in *Surgery*, was divided by the ancients into ſix branches, namely, ſyntheſis, diæreſis, exæreſis, aphæreſis, proſtheſis, and diorthroſis. Exæreſis implied all ſuch methods and operations, as had for their object the removal of diſeaſed, redundant, or extraneous ſubſtances from the body.

EXAGGERATION, in *Rhetoric*, a figure whereby we enlarge or heighten things; making them appear more than they really are, whether as to goodneſs, badneſs, or other qualities.

The word is formed of the Latin *exaggero, I exaggerate;* which is a compound of *ex* and *agger, a mound*, or *elevation of earth*. See Hyperbole.

Exaggeration, in *Painting*, is a method of repreſenting things, wherein they are loaded too much, or marked too ſtrongly; whether in reſpect of the deſign, or the colouring, or the poſition of the object.

Exaggerating differs from caricaturing, in that the latter perverts, or gives a turn to the features, &c. of a face which they had not; whereas the former only improves, or heightens what they had.

The latter is a kind of burleſque on the object, and is generally meant to ridicule: the former is uſually an exalting or enlivening of the beauties of the object, beyond what nature allows. The painter is obliged to have recourſe to an exaggeration of colours, both on account of the ſurface of his ground, the diſtance of his work, and of time, and the air, which diminiſh and weaken the force of the colours; but this exaggeration muſt be conducted in ſuch a manner, as not to put the objects out of their natural characters. The term exaggeration is not now in uſe. See Style in *Painting*.

EXAGON. See Hexagon.

EXA'LMA, from εξαλλω, *to leap out*, in *Surgery*, a diſlocation of the vertebræ, according to Hippocrates.

EXALTACION, in *Geography*, a town of South America, in the government of Moyes; 50 miles S. of Trinidad.

Exaltation *of the Croſs*. See *Exaltation of the* Croſs.

EXALTATION, Elevation, is chiefly uſed in a figurative ſenſe, for the raiſing or advancing a perſon to ſome eccleſiaſtical dignity; and particularly to the papacy.

The term exaltation is, in ſome meaſure, appropriated to the pope; and expreſſes his inauguration, coronation, taking poſſeſſion, and the beginning of his pontificate.

We ſhall here add, that the croſs was delivered up by a treaty of peace made with Siroes, Choſroes' ſon. The inſtitution of this treaty is commonly ſaid to have been ſignalized by a miracle; in that Heraclius could not ſtir out of Jeruſalem with the croſs, while he had the imperial veſtments on, enriched with gold, and precious ſtones; but bore it with eaſe, in a common dreſs.

But, long before the empire of Heraclius, there had been a feaſt of the ſame denomination obſerved both in the Greek and Latin churches, on occaſion of what our Saviour ſaid in St. John, xii. 32. "And I, if I be exalted, or lifted up, will draw all men unto me." And again, in ch. viii. ver. 28. "When ye have exalted, or lifted up, the Son of man, then ſhall ye know that I am he." F. Du Soulier aſſures us, that M. Chaſtelain was of opinion, this feaſt had been inſtituted, at leaſt at Jeruſalem, two hundred and forty years before Heraclius.

The feaſt of the dedication of the temple built by Conſtantine, was held, ſays Nicephorus, on the fourteenth of September, the day on which the temple had been conſecrated, in the year 335; and this feaſt was alſo called the exaltation of the croſs, becauſe it was a ceremony therein, for the biſhop of Jeruſalem to aſcend a high place, built by Conſtantine for that purpoſe, in manner of a pulpit, called by the Greeks, the "ſacred myſteries of God," or, "the holineſs of God," and there hoiſt up the croſs, for all the people to ſee it.

Exaltation, in *Phyſics*, denotes the act, or operation, of elevating, purifying, ſubtilizing, or perfecting, any natural body, its principles and parts; alſo the quality, or diſpoſition, which bodies acquire by ſuch operation.

The term exaltation has been peculiarly affected by the ancient chemiſts and alchemiſts; who imagining it to have ſome extraordinary emphaſis, are employing it on every occaſion.

Exaltation, in *Aſtrology*, is a dignity which a planet acquires in certain ſigns, or parts of the zodiac; which dignity is ſuppoſed to give it an extraordinary virtue, efficacy, and influence. The oppoſite ſign, or part of the zodiac, is called the dejection of the planet.

Thus, the 15th degree of Cancer is the exaltation of Jupiter, according to Albumazar, becauſe it was the aſcendant of that planet at the time of the creation; that of the ſun is in the 19th degree of Aries; and its dejection in Libra; that of the moon is in Taurus, &c. Ptolemy gives the reaſon of this in his firſt book De Quadrup.

EXAMEN, or Examination, an exact and careful ſearch, or inquiry, in order to diſcover the truth or falſehood of a thing.

EXAMILION, &c. See Hexamilion, &c.

EXAMINATION, Self, is a point much inſiſted on by divines, and particularly the ancient fathers, by way of preparation to repentance. St. Ignatius reduces it to five points; *viz.* 1. A returning of thanks to God for his benefits. 2. A begging of grace and light, to know and diſtinguiſh our ſins. 3. A running over all our actions, occupations, thoughts, and words, in order to learn what has been offenſive to God. 4. A begging of pardon, and conceiving a ſincere ſorrow for having diſpleaſed him. And, 5. Making a firm reſolution not to offend him any more; and taking the neceſſary precautions to preſerve ourſelves from it.

Examination *of Bankrupt*, in *Law*. See Bankrupt.

Examination *of Priſoners*. See Commitment.

Examination, or Inspection, *Trial by*, is when, for the greater expedition of a cauſe, in ſome point or iſſue being either the principal queſtion, or ariſing collaterally out of it, but being evidently the object of ſenſe, the judges of the court, upon the teſtimony of their own ſenſes, ſhall decide the point in diſpute. Thus, in caſe of a ſuit to reverſe a fine for non-age of the cognizor, or to ſet aſide a ſtatute or recognizance entered into by an infant; in this, and in ſimilar caſes, a writ ſhall iſſue to the ſheriff (9 Rep. 31.), commanding him that he conſtrain the ſaid party to appear, that it may be aſcertained by the view of his body by the king's juſtices, whether he be of full age or not. If, however, the court, upon inſpection, has any doubt of the age of the party, it may proceed to take proofs of the fact; and, particularly, may examine the infant himſelf upon an oath of *voir dire, veritatem dicere*, that is, to make true anſwer to ſuch queſtions as the court ſhall demand of him; or the court may examine his mother, his godfather, or the like. (2 Roll. Abr. 573.) In like manner, if a defendant pleads in abatement of the ſuit that the plaintiff is *dead*, and one appears and calls himſelf the plaintiff, which the defendant denies; in this caſe the judges ſhall determine, by inſpection and examination, whether he be the plaintiff or not. (9 Rep. 30.) Alſo, if a man be found by a jury an idiot, *à nativitate*, he may come in perſon into the chancery before the chancellor, or be brought there by his friends, to be inſpected and examined, whether idiot or not; and if, upon ſuch view and inquiry, it appears he is not ſo, the verdict of the jury, and all the proceedings thereon, are utterly void and inſtantly of no effect. (Ibid. 31.) The trial by inſpection may be alſo uſed, upon an appeal of maihem, when the iſſue joined is whether it be maihem or no maihem, this ſhall be decided by the court upon inſpection, for which purpoſe they may call in the aſſiſtance of ſurgeons. (2 Roll. Abr. 578.) And by analogy to this, in an action of treſpaſs for maihem, the court (upon view of ſuch maihem as the plaintiff has laid in his declaration, or which is certified by the judges who tried the cauſe to be the ſame as was given in evidence to the jury) may increaſe the damages at their own diſcretion (1 Sid. 108.); as may alſo be the caſe upon view of an atrocious battery. (Hardr. 408.) But then the battery muſt likewiſe be alleged ſo certainly in the declaration, that it may appear to be the ſame with the battery inſpected. Alſo, to aſcertain any circumſtances relative to a particular day paſt, it hath been tried by an inſpection of the almanac by the court. Thus, upon a writ of error from an inferior court, that of Lynn, the error aſſigned was that the judgment given was on a Sunday, it appearing to be on the 26th February, 26 Eliz. and upon inſpection of the almanacs of that year, it was found that the 26th of February in that year actually fell upon a Sunday: this was held to be a ſufficient trial, and that a trial by a jury was not neceſſary, although it was an error in fact, and ſo the judgment was reverſed. (Cro. Eliz. 227.) But, in all theſe caſes, the judges, if they conceive a doubt, may order it to be tried by a jury. Blackſt. Com. vol. iii.

Examination *of witneſſes*, in the trial by jury, derives peculiar advantage from its being conducted openly, *vivâ voce*, in the preſence of all mankind. This mode of examination is much more conducive to the clearing up of truth, than the private and ſecret examination taken down in writing before an officer or his clerk, in the eccleſiaſtical courts, and all others that have borrowed their practice from the civil law, where a witneſs may frequently depoſe that in private, which he will be aſhamed to teſtify in a public and ſolemn tribunal. Beſides, the occaſional queſtions of the judge, the jury, and the counſel, propounded to the witneſſes on a ſudden, will ſift out the truth much better than a formal ſet of interrogatories previouſly penned and ſettled; and the confronting of adverſe witneſſes is alſo another opportunity of obtaining a clear diſcovery, which can never be had upon any other method of trial. Nor is the preſence of the judge, during the examination, a matter of ſmall importance; for, beſides the reſpect and awe with which his preſence will naturally inſpire the witneſs, he is able by uſe and experience to keep the evidence from wandering from the point in iſſue. In ſhort, by this method of examination, and this only, the perſons who are to decide upon the evidence have an opportunity of obſerving the quality, age, education, underſtanding, behaviour, and inclination of the witneſs; in which points all perſons muſt appear alike, when their depoſitions are reduced to writing, and read to the judge, in the abſence of thoſe who made them; and yet as much may be frequently collected from the manner in which the evidence is delivered as from the matter of it. See Evidence.

Examination *of witneſſes* in Chancery is done with a view to the proof of facts that are diſputed, and their depoſitions are taken in writing, according to the manner of the civil law. For this purpoſe interrogatories are formed or queſtions in writing; which, and which only, are to be propoſed to, and aſked of, the witneſſes in the cauſe. For the examination of witneſſes in or near London, there is an examiner's office appointed; but for ſuch as live in the country, a commiſſion is granted to four commiſſioners, two named on each ſide, or any three or two of them, to take the depoſitions there. And if the witneſſes reſide beyond ſeas, a commiſſion may be had to examine them there upon their own oaths, and (if foreigners) upon the oaths of ſkilful interpreters. And it hath been eſtabliſhed that the depoſition of an heathen who believes in the Supreme Being, taken by commiſſion in the moſt ſolemn manner according to the cuſtom of his own country, may be read in evidence. The commiſſioners are ſworn to take the examinations truly and without partiality, and not to divulge them till publiſhed in the court of chancery; and their clerks are alſo ſworn to ſecrecy. The witneſſes are compellable by proceſs of *ſubpœna*, as in the courts of common law, to appear and ſubmit to examination. And when their depoſitions are taken, they are tranſmitted to the court with the ſame care that the anſwer of a defendant is ſent. See Commission *to examine witneſſes*, and Interrogatories.

EXAMINERS, in *Chancery*, are two officers, whoſe buſineſs is to examine, on oath, the witneſſes produced on both ſides, upon ſuch interrogatories as the parties to the ſuit do exhibit for the purpoſe.

EXAMPLE, in *Rhetoric*, denotes an imperfect kind of induction or argumentation; whereby it is proved, that a thing which has happened on ſome other occaſion, will happen again, on the preſent one, from the ſimilitude of the caſes. That is uſually called an example, which is brought either to prove or illuſtrate ſome general aſſertion, as if one ſhould ſay, that "human bodies may be brought to ſuſtain the greateſt labours by uſe and exerciſe:" and in order to prove this ſhould relate what is ſaid of Milo of Croton, that "by the conſtant practice of carrying a calf ſeveral furlongs every day, he ſhould carry it as far after it was grown to its full ſize." (Eraſm. Chil. p. 193.) But the word example is uſed in oratory for any kind of ſimilitude; or, as Voſſius defines it (Orat. Partit. l. iii. c. 7. § 16.), "When one thing is inferred from another, by reaſon of the likeneſs which appears between them." Hence it is called an "imperfect induction," which infers ſomething from ſeveral others of a like nature. With regard to examples, we may obſerve, that thoſe have the greateſt force in reaſoning, which are taken from facts. See Induction.

EXANIA, from *ex*, *out of*, and *anus*, the complaint now more commonly named by practitioners in ſurgery prolapſus ani. See Prolapsus.

EXANNUAL Roll. In the old way of exhibiting ſheriff.'s accounts, the illeviable fines and deſperate debts were tranſcribed into a roll, under this name, which was yearly read, to ſee what might be gotten by it.

EXANTHEMA, in *Medicine*, ſynonymous with *effloreſcence*, from εξ, and ανθος, *a flower*, a term applied by the older writers nearly in the ſame ſenſe in which we now employ the word *eruption*, and comprehending every ſpecies of ſpot, diſcolouration, or elevation of the ſkin. The ſyſtematic noſologiſts at preſent underſtand by this word all eruptions on the ſkin, which are accompanied with fever; ſuch as the ſmall-pox, meaſles, ſcarlet fever, &c. Dr. Willan uſes the term in a more limited ſenſe, *viz.* to expreſs that appearance only which is in Engliſh denominated a *raſh*; which is a bluſh or "redneſs of the ſkin, varying as to extent, continuity, and brightneſs of colour, and occaſioned by an unuſual quantity of blood diſtributed to ſeveral of the cutaneous veins, in ſome inſtances with partial extravaſation." The exanthemata conſtitute the third order of Dr. Willan's claſſification of cutaneous diſeaſes, including the meaſles, ſcarlet fever, nettle-raſh, roſeola, purpura, and erythema. See Cutaneous *diſeaſes*, and theſe words reſpectively. See alſo Cullen Noſol. Method. claſs i. order iii. Willan on Cutan. Diſ. ord. iii.

EXARCH, Εξαρχος, in *Antiquity*, an appellation given, by the emperors of the Eaſt, to certain officers ſent into Italy, in quality of vicars, or rather prefects, to defend that part of Italy which was yet under their obedience; particularly the city of Ravenna, againſt the Lombards, who had made themſelves maſters of the greateſt part of the reſt.

The reſidence of the exarch was at Ravenna; which city, with that of Rome, were all that was left to the emperors. The firſt exarch was Longinus, who was ſent in the year 568 by the emperor Juſtin II. the ſucceſſor of Juſtinian, to govern Italy in the room of Narſes. Longinus, being inveſted with abſolute authority and power, ſuppreſſed the magiſtrates, who had been previouſly appointed to govern the provinces of Italy; and he himſelf took the title of exarch, which by the Greeks was given to thoſe who preſided over a dioceſe, and conſequently over the numerous provinces of which the dioceſe was compoſed. This title was adopted by the ſucceſſors of Longinus, who, reſiding, as he had done, at Ravenna, were on that account called the exarchs of Ravenna. They governed all Italy, naming and removing the magiſtrates, called dukes, at their pleaſure; and to them the people had recourſe in all matters of conſequence. Longinus was ſent by Juſtin to rule all Italy; but a great part of that country, in the firſt year of his government, was ſeized on by the Lombards, who had been called in by Narſes. This magiſtrate maintained the power and authority of the emperors of the Eaſt in Italy for the ſpace of 183 years, that is, from the year 568, when Longinus was ſent into Italy, to the year 751, when Eutychius, the laſt exarch, was expelled, and Ravenna taken by Aſtulphus, or Aſtolphus, king of the Lombards. See Lombards.

According to Gibbon (Decline and Fall of the Roman Empire, vol. vii.) Narſes was the firſt and moſt powerful of the exarchs, and adminiſtered above fifteen years the kingdom of Italy. A duke was ſtationed for the defence and military command of each of the principal cities of Italy; and the eye of Narſes pervaded the ample proſpect from Calabria to the Alps. During a period of 200 years, ſays the hiſtorian, (vol. viii.) Italy was unequally divided between the kingdom of the Lombards and the exarchate of Ravenna; and 18 ſucceſſive exarchs were inveſted, in the decline of the empire, with the full remains of civil, of military, and even of eccleſiaſtical power. Their immediate juriſdiction, which was afterwards conſecrated as the patrimony of St. Peter, extended over the modern Romagna, the marſhes or vallies of Ferrara and Commachio, five maritime cities from Rimini to Ancona, and a ſecond, inland Pentapolis, between the Adriatic coaſt and the hills of the Apennines. Three ſubordinate provinces, of Rome, of Venice, and of Naples, which were ſeparated by hoſtile lands from the palace of Ravenna, acknowledged, both in peace and war, the ſupremacy of the exarch. The remainder of Italy was poſſeſſed by the Lombards. When Aſtulphus, as we have already mentioned, had made himſelf maſter of the exarchate, he thought that he had a juſt title to all the places depending on that domain, and conſequently to the Roman dukedom and to Rome itſelf. He, therefore, required by a meſſenger the inhabitants of that city to acknowledge him for their ſovereign; and at the ſame time began his march towards Rome. The pope, Stephen II., was alarmed, and attempted to divert Aſtulphus from his declared purpoſe of plundering Rome and maſſacring the inhabitants, by a ſolemn embaſſy; but the king, rejecting the preſents accompanying this embaſſy, inſiſted upon being acknowledged by the pope and the Romans for their ſovereign. The pope in this diſtreſs applies to the emperor; but Conſtantine was not in a condition to aſſiſt him. He then determined to recur to the protection of France, which had been transferred, ſome years before, from the Merovingian to the Carlovingian line; and the celebrated Pepin, ſon to Charles Martel, was then king. Indeed Pepin had previouſly promiſed to pope Zachary, that he would protect his ſee againſt all its enemies, eſpecially againſt the Lombards. Pope Stephen viſited France in perſon; and having ſtated the deplorable condition to which he was reduced by the Lombards, and implored his aſſiſtance and protection, Pepin promiſed to aſſiſt him againſt the Lombards with the whole ſtrength of his kingdom, and to drive them out of the exarchate and Pentapolis, which were to be reſtored, as Pepin underſtood, to the emperor, from whom the Lombards had taken them; but the pope, finding the king well-diſpoſed, took advantage of this favourable opportunity for aggrandizing himſelf; and, therefore, inſinuated to Pepin, that he could not better acquit himſelf of his obligations to the apoſtolic ſee, conſult the welfare of his ſoul, or reward him for the dangers he had undergone, and the pains he had taken for the ſafety of Italy, and the church, than by granting both the exarchate and Pentapolis to St. Peter, that is, to himſelf. The pope, at the ſame time, pretended that Conſtantine had forfeited all right to thoſe countries, by forſaking the protection of Italy, and perſecuting the church. Pepin not only put him in poſſeſſion of the exarchate and Pentapolis, if he ſhould ſucceed in expelling the Lombards, but confirmed his promiſe with an oath, in which his ſons Charles and Carloman concurred. In conſequence of this engagement Pepin marched with his army againſt the Lombards, and having routed them, Aſtulphus fled precipitately to Pavia. Pepin purſued him, and having beſieged his capital, granted him peace on condition of his reſtoring the places which he had ſeized in the Roman dukedom, together with the exarchate and Pentapolis, to the pope. Hoſtages were alſo delivered in order to ſecure the fulfilment of this condition. Aſtulphus, regardleſs of his oath and hoſtages, invaded the Roman dukedom, ſeized ſeveral cities, and beſieged Rome itſelf. In this extremity, Stephen had again recourſe to his protector, who, highly incenſed at the treachery of Aſtulphus, marched again into Italy, and cloſely inveſted Pavia, into which the Lombard king had retired. Aſtulphus once more ſued for peace, which was granted him upon his promiſing to perform immediately the treaty made the year before, and, beſides, to ſurrender to the pope the city of Commachio, which was then a place of great importance. Pepin then renewed his donation; and having cauſed a new inſtrument to be drawn up, he cauſed it to be delivered, ſigned by himſelf, by his two ſons, Charles and Carloman, and by the chief barons and prelates of France, into the pope's hands. He then left Italy, and returned with his army to France. The exarchate compriſed, according to Sigonius (ad ann. 756) the following cities, *viz.* Ravenna, Bologna, Imola, Faenza, Forlimpopoli, Forli, Ceſena, Bobbio, Ferrara, Commachio, Adria, Servia, and Secchia, which were all delivered to the pope, except Faenza and Ferrara. Pentapolis, or Marca d'Ancona, comprehended Rimini, Peſaro, Conca, Fano, Sinigaglia, Ancona, Oſimo, Umana, Jeſi, Foſſombrone, Monteferetro, Urbino, the Balneſian territory, Cagli, Lucceoli, and Eugubio, with their territories and diſtricts, as appears by the donation of Lewis the Pious, by which Pepin's donation was confirmed. The pope committed the government of the exarchate to the archbiſhop of Ravenna, who thereupon took the title of exarch, not as archbiſhop, but as an officer of the pope, now a temporal prince. Thus was the ſceptre added to the keys, the ſovereignty to the prieſthood, and the popes were enriched with the ſpoils of the Lombard kings, and the Roman emperors. As thoſe countries belonged, without doubt, to Conſtantine their emperor, ſome authors have thought that this donation was made in his name, and that this gave riſe to the fable of the donation of Conſtantine the Great. Hence it appears that the popes by degrees became ſovereigns of Rome. The exarchate of Ravenna, ſays Petrus de Marca, being yielded to the pope, the government of Rome, of courſe, devolved upon him; for the Roman dukedom had been always ſubject to the exarch. The pope, therefore, when he became maſter of the exarchate, claimed the adminiſtration, and continued to govern Rome, not as ſovereign, but only with the authority that had been veſted in the exarch, till the year 876, when the authority of the emperors, ſucceſſors of Charlemagne, declining in Italy, Charles the Bald yielded all his claim to, and ſovereignty over Rome, to the apoſtolic ſee. Hence Conſtantine Porphyrogenitus, deſcribing the ſtate of Europe in his time, that is, about the year 914, writes, that Rome was ſubject to the pope, as its ſovereign. It was upon the decleuſion of the weſtern empire, when it was confined to Germany alone, that the pope, as well as the ſeveral princes of Italy, aſſumed the ſovereignty, which they afterwards enjoyed. The donation of Pepin was confirmed by Charlemagne at the requeſt of pope Adrian; for having ordered Iterius, his ſecretary, to draw up a new inſtrument, he ſigned it himſelf, cauſed it to be ſigned by the abbots, biſhops, and other great men, who had attended him to Rome, and, with his own hand, laid it on the altar of St. Peter.

F. Papebroch, in his Propylæum ad Acta Sanct. Maii, has a diſſertation on the power and office of the exarch of Italy, in the election and ordination of the pope.

The emperor Frederic created Heraclius, archbiſhop of Lions, a deſcendant of the illuſtrious houſe of Montboiſſier, exarch of the whole kingdom of Burgundy; a dignity, till that time, unknown any where but in Italy, particularly in the city of Ravenna. Meneſtrier. Hiſt. de Lyons.

Homer, Philo, and other ancient authors, give likewiſe the name exarchus to the choragus, or maſter of the ſingers, in the ancient choruſes, or him who ſung firſt; the word *αρχειν*, or *αρχομαι*, ſignifying equally *to begin*, and *to command*

Exarch *of a dioceſe*, was anciently the ſame with primate. This dignity was inferior to the patriarchal, yet greater than the metropolitan.

Exarch alſo denotes an officer ſtill ſubſiſting in the Greek church; being a kind of deputy or legate *a latere* of the patriarch, whoſe office it is to viſit the provinces allotted him, in order to inform himſelf of the lives and manners of the clergy; take cognizance of eccleſiaſtical cauſes; the manner of celebrating divine ſervice; the adminiſtration of the ſacraments, particularly confeſſion; the obſervance of the canons; monaſtic diſcipline; affairs of marriages, divorces, &c. but, above all, to take an account of the ſeveral revenues which the patriarch receives from ſeveral churches; and particularly as to what regards the collecting of the ſame.

The exarch, after having greatly enriched himſelf in his poſt, frequently riſes to the patriarchate itſelf.

Exarch is alſo uſed, in the *Eaſtern Church Antiquity*, for a general, or ſuperior over ſeveral monaſteries; the ſame that we otherwiſe call archimandrite: being exempted, by the patriarch of Conſtantinople, from the juriſdiction of the biſhops; as are now the generals of the Romiſh monaſtic orders.

In 493, Sebas was eſtabliſhed exarch, or chief, of all the anchorets within the territory of Jeruſalem. Du Bois.

EXA'RMA, from *εξαιρομαι*, *to be elevated*, in *Surgery*, a high, prominent, ſwelling.

EXARTHREMA, from *εξ*, *out of*, and *αρθρον*, *a joint*, an old term, having the ſame ſignification as the word diſlocation. See Luxation.

EXA'RTHROS, from *εξ*, *out of*, and *αρθρον*, *a joint*, a term denoting a perſon whoſe joints are ſo large and miſ-ſhapen, that they look as if they were luxated.

EXARTICULATION, a diſlocation of ſome of the jointed bones; or a breach of articulation. See Luxation.

EXAUCTORATIO, among the Romans, differed from *miſſio*, or a diſcharge. In the latter, the ſoldiers were quite diſmiſſed from the ſervice; and this was done after they had ſerved twenty years: but in the former caſe, they only loſt their pay, being ſtill kept under their colours or *vexilla*, though not under the eagle, *aquila*, which was the ſtandard of the legion. Whence, inſtead of *legionarii*, they were called *ſubſignani*, and were ſtill retained till they had either ſerved out their time, or had lands aſſigned them. The exauctoratio commonly took place after they had ſerved ſeventeen years.

EXAUDET, in *Biography*, a performer on the violin in the opera band at Paris from 1749 to 1760; remarkable for nothing as a compoſer, but for the minuet which bears his name in France, and which in England is better known by the title of "Marſhal Saxe's Minuet," the beſt "Minuetto per ballo," or for dancing, perhaps, that ever was compoſed.

EXCALCEATION, *ex*, *off*, and *calceus*, *ſhoe*, *diſcalceation*, or the act of putting off the ſhoes.

Among the Hebrews there was a particular law, whereby a widow, whom her huſband's brother refuſed to marry, had a right to ſummon him into a court of juſtice; and, upon his refuſal, might excalceate him, *i. e.* pull off one of his ſhoes, and ſpit in his face; which were both actions of great ignominy among that people.

The houſe of the perſon who had undergone them was thenceforward called the houſe of the excalceated.

EXALCED, Excalceati, different orders of friars, hermits, and nuns, who amongſt their other auſterities went barefooted, or wore nothing on their feet but ſandals, were diſtinguiſhed by the name of excalced, as the Franciſcans, Carmelites, Poor Clares, &c. whilſt other branches of the ſame inſtitute, but leſs rigid, were called calced, from their members wearing ſhoes. A particular branch of the Waldenſes, Vaudois, or poor men of Lyons, in the 12th century, laid great ſtreſs on the wearing of ſabots or wooden clogs inſtead of ſhoes, and therefore obtained the name of Sabatati and Inſabatati.

EXCAMBIATOR. See Excambio, and Exchange.

EXCAVATION, formed of *ex*, and *cavus*, *hollow*, or *cave*, a *pit*, &c. the act of hollowing or digging a cavity, particularly in the ground.

The excavation of the foundations of a building, by the

Italians called *cavatione*, is ſettled by Palladio at a ſixth part of the height of the whole building: unleſs there be cellars underground, in which caſe he would have it ſomewhat more.

EXCAVATION *of Vallies*, in *Geology*, is a ſubject which has exerciſed the thoughts of many ingenious men, the greater part of whom have ſuppoſed that theſe ſtupendous and important operations were effected by violent currents of water, which at ſome period made their way down them: but a more careful examination has ſhewn, that in ſcarcely any inſtances are the excavated materials to be found, or any part of them, as muſt inevitably have happened at the bends and junctions of vallies, particularly thoſe which lie far inland, had the mere waſhing of water been the cauſe of vallies: but Mr. Farey, and Dr. William Richardſon, have of late, and ſeparately as it ſhould ſeem, come to the concluſion (Philoſophical Magazine, vol. xxxiii. p. 204 and 262.) that theſe excavations were effected by cauſes acting "from above the ſurface of the earth," which completely carried off the matter which once filled up the vallies, and originally joined thoſe correſponding parts of ſtrata, whoſe edges are now in a great number of inſtances to be traced in their oppoſite ſides: theſe opinions of the former gentlemen have been already ſlightly noticed, and referred to, in our articles COAL, COLLIERY, and others.

EXCELLENCY, a quality, or title of honour given to ambaſſadors, and other perſons, who are not qualified for that of highneſs, as not being princes; and yet are to be elevated above the other inferior dignities.

In England, and France, the title is now peculiar to ambaſſadors: but it is very common in Germany and Italy. Thoſe to whom it was firſt appropriated were the princes of the blood of the ſeveral royal houſes; but they quitted it for that of highneſs, upon ſeveral great lords aſſuming excellency.

The ambaſſadors have only borne it ſince the year 1593, when Henry IV. of France ſent the duke de Nevers ambaſſador to the pope, when he was firſt complimented with excellency. After that, the ſame appellation was given to all the other ambaſſadors reſiding at that court; from whence the practice ſpread through the other courts.

The ambaſſadors of Venice have only had it ſince the year 1636, when the emperor and king of Spain conſented to allow it them.

The ambaſſadors of the crowned heads diſpute the giving of that title to the ambaſſadors from the princes of Italy; where the practice is not eſtabliſhed.

The court of Rome never allowed the quality of excellency to any ambaſſador who was a churchman, as judging it a ſecular title. The common rules and meaſures of excellency were a little variable, with reſpect to the court of Rome. The ambaſſadors of France, at Rome, anciently gave the title of excellency to all the relations of the pope then reigning; to the Conſtable Colonna; to the duke of Bracciano, and the eldeſt ſons of all thoſe lords; as alſo the dukes of Savelli, Ceſarini, &c. But they have been ſince more reſerved in this reſpect; though they ſtill honoured all the Roman princeſſes with excellency.

The court of Rome, in their turn, and the Roman princes, beſtowed the ſame title on the chancellor, miniſters, and ſecretaries of ſtate, and preſidents of the ſovereign courts of France; the preſidents of the councils in Spain; the chancellor of Poland; and thoſe of the firſt dignities of other ſtates, if they were not eccleſiaſtics.

The word excellency was, anciently, a title of kings and emperors; accordingly Anaſtaſius the library-keeper calls Charlemagne his excellency. The ſame title is ſtill given to the ſenate of Venice: where, after ſaluting the doge under the title of *ſereniſſimo*, the ſenators are addreſſed under thoſe of your *excellencies*. The Liber Diurnis Pontif. Rom. gives the title excellency to the exarch and patricians.

The Italian and French have improved on ſimple excellency; and made *excellentiſſimo*, and *excellentiſſime*, which have been beſtowed on certain popes, kings, &c.

EXCELSIS. See GLORIA *in excelſis*.

EXCENTRIC, in *Geometry*, is applied where two circles, or ſpheres, though contained, in ſome meaſure, within each other, yet have not the ſame centre; and, conſequently, are not parallel; in oppoſition to concentric, where they are parallel, having one and the ſame common centre. The ſun's orbit is excentric, with regard to the globe of our earth: Mars is very excentric, with regard to the ſun; that is, his motion is about a very different centre.

EXCENTRIC *Theory*, in *Ancient Aſtronomy*, one of the theories adopted by the ancient aſtronomers to explain and calculate the different irregularities which they had obſerved to take place in the motions of the heavenly bodies.

It is not exactly aſcertained at what period practical aſtronomy had attained ſufficient perfection to indicate the neceſſity of ſuch a theory. Probably both the Indian and Egyptian aſtronomers were early acquainted with the more obvious inequality in the ſun's orbit; but Hipparchus is the firſt aſtronomical writer who ſeems to have aimed at determining it with any degree of preciſion.

The theory embraced by Hipparchus is ſaid to have been firſt taught in Greece by the diſciples of Pythagoras. Though their knowledge on the ſubject is ſuppoſed to have been derived from the oriental nations, yet it is highly probable they contributed to ſtrengthen the prejudices in favour of circular and uniform motion, which afterwards proved the ſource of ſo much difficulty and error in all the ſyſtems of ancient aſtronomy. It was from this prejudice, early aſſumed as a principle, that nature could not, conſiſtently with the obſerved ſimplicity of her deſigns, adopt any other form for the celeſtial orbits than that of perfect circles, nor any other motion than what was perfectly uniform. The problem, therefore, that occupied the aſtronomers and philoſophers of thoſe days, was to explain the various irregularities which they obſerved in the planetary motions, without infringing on the above principle.

There were two theories choſen for this purpoſe, nearly equivalent in their principle, the concentric and the excentric.

In the concentric theory the earth was ſuppoſed to be placed in the centre of a circle, on the circumference of which the centre of another circle revolved, and on the circumference of this ſecond circle, called an epicycle, the planet was ſuppoſed to move. The firſt circle was called the *deferent*, and by aſſigning a ſuitable ratio to the deferent circle, and to its correſponding epicycle, ſome of the more obvious irregularities were pretty accurately repreſented. *Fig.* 110. *Plate* XIII. *Aſtronomy*, is the repreſentation of the concentric theory. Let C be the centre both of the earth and of the circle F B D, and let H G K be a ſmaller circle, or epicycle, whoſe centre B moves uniformly in the circumference F B D, from weſt to eaſt, or *in conſequentia*, while the ſun moves alſo uniformly and with the ſame velocity in the circumference of the epicycle, *in antecedentia* in the upper part, but *in conſequentia* in the lower part. If the point G of the epicycle, called its apogee, as being moſt diſtant from the earth, be ſuppoſed at the beginning of the anomaliſtic revolution to be placed in the point A of C F produced; and if when it comes to G, the arc G H be taken ſimilar to F B, the point H will be the place of the ſun when the centre of the epicycle has moved from F to B. If then in C F, to which B H is parallel, we take C E = B H, and on E as a centre, with the diſtance E A = C F, deſcribe the circle A H P, the ſun would be ſeen from E to move in this circle equably; for the angle A E H is equal to the angle F C B; but ſeen from C, the centre of the earth, it will appear to move in it inequably; for the angle A C H, in the firſt circle of anomaly, that is, in the paſſage of the ſun from A to P, is always leſs than A E H or F C B; and its true place H will be leſs advanced in longitude than its mean place B. When again the centre of the epicycle or the mean place of the ſun, having deſcribed a ſemicircle, ſhall have come to D, the ſun, having deſcribed a ſemicircle of the epicycle, will be found in P, the perigee of the orbit A H P, and its mean and true places B and H will be ſeen from C to coincide as they did in the apogee A. But in the ſun's paſſage from P to A, that is, in the ſecond ſemicircle of anomaly, his true place H, as ſeen from C, will be always more advanced in longitude than his mean place B: for in this ſemicircle the angle P C H is always greater than P E H or D C B. The angle E H C or B C H, which is the difference between the mean and true places of the ſun, is called the equation of the orbit, and it is evident that this equation will be greateſt in N or M, where the centre B of the epicycle is 90° diſtant from either of the apſides.

It was thus that the ancients originally proceeded in their repreſentation of the ſolar inequalities, and the repreſentation ſeemed to be ſufficiently juſtified by obſervation: at leaſt, till the days of T. Brahé, no obſervations had been made with ſufficient accuracy to ſubject it to ſuſpicion. Their ſucceſs alſo, while no lunar inequality except the ſimple anomaliſtical one was diſcovered, was equal in the application of the ſame concentric theory to the motions of the moon: and having, in two caſes, thus ſucceſsfully, by means of one ſubordinate ſphere or epicycle, reconciled apparent inequality of motion with real uniformity, it was natural to ſuppoſe that other inequalities, though more various and complicated, might be explained in a ſimilar manner, and required only the addition of other epicycles. The ſame method of procedure, therefore, was continued, and every new inequality which obſervation diſcovered, was accounted for by a new ſphere or epicycle producing it, till the whole number employed in the ſyſtem amounted to 34. Ariſtotle, on narrower examination, found theſe inſufficient, and added to them 22: but ſtill they were deemed inſufficient; and the number was at laſt increaſed to 72. But though it was not till long after the days of Ariſtotle, that the theory was carried to ſuch a degree of extravagance, the multiplication of epicycles rendered it, even in his time, almoſt as intricate and complex as the appearances which it was intended to explain. Some examples of this kind will occur on the revival of it by Copernicus and T. Brahé: and when Hipparchus and Ptolemy introduced excentric orbits, and by means of them ſomewhat diminiſhed the multiplicity of the ſpheres employed by their predeceſſors, they were thought to do a ſignal ſervice to aſtronomy.

The manner in which Hipparchus explained the ſolar inequalities, in his excentric theory, was to this purpoſe. Let O (*fig.* 111.) be the centre of the earth and of the ſtarry ſphere. Let B C D E be the ecliptic, or great circle in the *primum mobile* in which the ſun ſeems to perform his annual revolutions; and, in the ſame plane, but on a different centre Z, let the circle A L P be deſcribed. This is the circle, or orbit, in which the ſun is ſuppoſed actually to move, and to deſcribe round its centre equal arcs or angles in equal times: or rather, he is ſuppoſed to be carried round by the equable motion of the circle itſelf; which, becauſe its centre is not occupied by the earth, is called an excentric circle. It is evident, in this repreſentation, that if the earth were placed in Z, a ſpectator on it would perceive the ſun, ſince he is ſuppoſed to move uniformly in the excentric, to move alſo uniformly in the ecliptic. But the earth is placed in O, at the diſtance O Z from the centre of the excentric; and therefore, when his motions are referred to the ecliptic by a ſpectator in O, they muſt appear unequal. When, for example, he departs from A the apogee of the excentric, and comes to K, he would be ſeen from Z in the point R of the ecliptic; but from O, the centre of the earth, he is ſeen in C, a point leſs advanced in longitude. On the contrary, when he departs from P, the perigee of the excentric, and comes to N, his place in the ecliptic, as ſeen from Z, is the point V; but ſeen from O it is the point F, more advanced in longitude than V. Any line, as Z K, drawn from the centre of the excentric to the ſun, or any parallel to it drawn from O, is called the line of mean motion, and determines the mean anomaly A Z K; and any line, as O K, drawn from the ſun to the centre of the earth, is called the line of true motion, and determines the true anomaly A O K; and the angle O K Z, which is the difference between the mean and true anomalies, is the equation of the orbit. In the apogee and perigee this equation vaniſhes, in the ſame manner as in the concentric theory; becauſe there the lines of mean and true motion coincide; and at the points L, L, where a perpendicular to the line of apſides, drawn through O, meets the excentric, it comes to its greateſt amount. Thus, by the ſingle ſuppoſition that the ſolar orbit was excentric to the earth, Hipparchus ſupplied the place of the epicycle added to the concentric: nor is it difficult to perceive that the repreſentations, given by both theories of the ſolar inequalities, were in their effects preciſely the ſame.

In both theſe theories, it is evident that the inequalities of the ſun were conſidered as purely optical: and what was principally required was to find the point O, in the line A P of the apſides, in which the earth muſt be ſituated, in order to give to the ſolar motions the juſt inequality which obſervation required; and to determine the longitude A of the ſolar apogee, that is, the point B of the ecliptic to which it is referred from O. Without finding the juſt excentricity O Z, the calculated differences, or equations, between the ſun's mean and true places, would not correſpond with the obſerved differences: and without diſcovering the poſition of the apogee, the calculated equations, however accurate, would not be applied in their proper places. In theſe inveſtigations the procedure of Hipparchus was as follows.

Let B (*fig.* 112.) be the place of the ſun at the vernal equinox, B D an arc of the excentric equal to his mean motion for 94½ days, that is, from the vernal equinox to the ſummer ſolſtice, D F an arc equal to his mean motion for 92½ days, or from that ſolſtice to the autumnal equinox: let the chord B F be drawn, and from D another chord D E G perpendicular to B F. The point E of the interſection of theſe chords is evidently the point where the earth muſt be ſituated: for it is the only point from which B, D, F, G, can appear at the diſtance of 90° from one another, and as they appear actually in the heavens.

It was required, therefore, to determine the excentricity E C, or the diſtance of the point E from C, the centre of the ſolar orbit. Since the arc B D F of the mean motion, and which the ancients ſuppoſed to be the only real motion of the ſun, from B the vernal to F the autumnal

nal equinox, is given by means of the annual revolution, and conſiſts of 184° 20′, its half B H will conſiſt of 92° 10′. Through H draw the diameter H C; and through C the centre of the orbit, the diameter C K perpendicular to H C, and meeting D E in L; and join C E. If from B D, the mean motion for $94\frac{1}{2}$ days, and = 93° 9′ we ſubtract B H = 92° 10′, the remainder D H will be found = 59′: and if from B H we ſubtract the quadrant K H, the remainder B K will be = 2° 10′. Therefore C L and E L, the ſines of the arcs D H, B K, will be given in parts of C D = 10,000; the former to wit = 172, and the latter = 378. Therefore the excentricity E C, being the hypothenuſe of the right-angled triangle E L C, will be found in the ſame parts: for $EC^2 = CL^2 + EL^2$, and therefore E C = 415.

By producing E C to meet the excentric in A and P, we ſhall have the line A P of the apſides: and the longitude of A the apogee will be found from the ſame triangle E L C; for C E : E L :: R : ſin. E C L = K C A = B E A = 65° 30′. Since B therefore repreſents the point of Aries, the place A of the apogee fell ſhort of the ſolſtitial point D, 24° 30′, in the days of Hipparchus. It is now between 9° and 10° more advanced.

When the excentricity and the longitude of the apſides were thus determined, the equations of the orbit, or the differences between the mean and true places of the ſun, were obtained by a very ſimple trigonometrical computation. For in the excentric theory, (*fig.* 111.) when this equation comes to its greateſt magnitude, in the points L, L, or M, M, where perpendiculars to the line of apſides drawn through O or Z meet the excentric, the excentricity O Z becomes the tangent of the angle Z M O to the radius of the orbit Z M: and at any other point K, with the excentricity O Z, the radius Z K, and the angle K Z O the ſupplement of the mean anomaly A Z K, the equation Z K O will be found by the analogy K Z + Z O : K Z − Z O :: tan. $\frac{1}{2}$ A Z K : tan. $\frac{1}{2}$ (Z O K − Z K O). The calculation will be preciſely the ſame in the concentric theory if E C be taken in C A, (*fig.* 110.) equal to the radius of the epicycle, that is, to the excentricity O Z, (*fig.* 111.) and will produce the ſame reſults: and the excentric theory will be found to differ from the concentric only in ſimplicity. It is probably needleſs to obſerve that the parallels O L and Z M will mark the ſame point in the zodiac.

Though theſe theories were thought ſufficient to explain the ſolar motion, in that imperfect ſtate of practical aſtronomy, yet they were found entirely to fail when applied to the obſerved motions of the moon and planets. A new ſcheme was therefore adopted by Ptolemy, in which, however, the principle of uniform motion was in fact abandoned. This conſiſted in aſſuming an imaginary point as the centre of a new circle, called the equant; and it was ſuppoſed that to a ſpectator ſituated in that point the motion of the planet would appear to be uniform. It is not now exactly known if the Greek aſtronomers invented this theory, or if they received it by tradition from the eaſtern nations, but it is a curious circumſtance to obſerve, in the hiſtory of the ſcience of aſtronomy, how very near the truth the ancients arrived by trial and obſervation; for their deferent circle and epicycle reduced the figure of the orbit really to an oval form, and the two points in which they placed the earth and the centre of the equant were many centuries afterwards diſcovered to be no other than the foci of an elliptic orbit. The true theory was kept out of ſight by an obſtinate adherence to an ancient prejudice, for what a ſingular method was nature ſuppoſed to take, in order to adhere to this principle of uniform and circular motion; after a number of unmeaning efforts, ſhe only accompliſhed an *apparent* uniform motion round an imaginary point, in which no ſpectator could ever poſſibly be placed to admire the beauty of the contrivance:

The mode of determining the equant was as follows.

Let A be the centre of the earth, (*fig.* 113.) ſuppoſe the centre of the world D, the centre of the orbit of a planet, or of the excentric circle, F K M L E, called the deferent, (ſee Epicycle.) Upon the point F is deſcribed the epicycle G Q, and above D a point E is aſſumed, equal to the excentricity A D, and from the point E another circle is deſcribed, R K O L R, of the ſame magnitude as the deferent. This ſecond circle is called the equant, becauſe the centre of the epicycle, which moves upon the deferent, has nevertheleſs an equal motion round the centre E of the equant, for the epicycle deſcribes its deferent with an unequal motion, which ſhould diſappear when referred to the centre of the equant, ſo that the angle, ſuch as F E I, formed by the line of apſides A F, and by the line drawn to the centre of the epicycle, arrived at I, may be always equal in equal times; for this reaſon Ptolemy calls the point E the point of equality. The angle F A I is the true anomaly of the excentric, the angle F E I the mean anomaly, and which is always formed at the centre of the equant.

Kepler had endeavoured to explain phyſically the cauſe of the equant, that is, why there ſhould be a point E different from the point D, about which the motion was regular and uniform, (Myſter. Coſmogr. c. 22.) He was perſuaded the cauſe was general, and that the equant muſt take place in the orbit of the earth, as well as in the other planets. Neither Tycho nor Copernicus had employed an equant, but Kepler was perſuaded that the points E and D in an excentric were not the ſame, particularly when Tycho informed him that the annual orbit, or excentric of the ſun, appeared to him not to be always the ſame.

Kepler ſuſpected that this variation aroſe from the point of equality not being the centre of the circle; and in the courſe of his inveſtigation of this queſtion, he was led to the diſcovery of the biſection of the excentricity in the caſe of the earth, whereas the ancients only admitted it in the caſe of the ſuperior planets. See Excentricity, *biſection of.*

EXCENTRICITY *of the Orbit of a Planet*, in *Aſtronomy*, is the diſtance between the centre and the focus of the ellipſe in which it revolves. The diſcovery of the excentricity in the orbits of the ſun and moon is attributed to Hipparchus, who wrote a treatiſe on this ſubject 150 years before our era.

The excentricity of the orbit is computed from the greateſt equation of the centre, by the following proportion: As 57° 17′ 44.″8, (the arc = rad.) is to half the greateſt equation, ſo is rad. = 1 to the excentricity. See Equation, and Elliptic *Motion.*

But when the greateſt equation has been found, and accurately determined by obſervation, the excentricity may be practically deduced by uſing the rule of falſe poſition, or by ſuppoſing the excentricity known, and finding by trial the greateſt equation correſponding to it

The excentricities of the planetary orbits are uſually calculated on a ſcale which ſuppoſes the mean diſtance of the earth from the ſun divided into one hundred thouſand parts, and the excentricity is expreſſed in proportional parts of that ſcale.

The following formula for calculating the excentricity is given by Lambert in the Ephem. de Berlin.

Let E be the greateſt equation of the centre, e the excentricity, make $\frac{E}{57.} = \alpha$.

The excentricity will then be expreſſed by the following ſeries.

$$e = \frac{1}{2}\alpha - \frac{11}{768}\alpha^3 - \frac{587}{93040}\alpha^5 - \frac{40583}{2642411520}\alpha^7 -, \&c.$$

The quantity α is always a ſmall fraction, particularly for the ſun; if we ſuppoſe with La Place, $E = 2^{\circ}.1409$ decimal for 1750. Then,

$$\alpha = \frac{2.1409}{63.6620} = 0.033629$$

$$\frac{1}{2}\alpha = 0.016814.$$

The ſecond term, $\frac{11}{768}\alpha^3$, is leſs than 0.000001, and may therefore be entirely neglected.

Table *of Excentricities according to different Authors.*

Planets.	Kepler.	Caſſini.	Halley.	La Lande.	Log. of Excen. in parts of the mean diſtance
Mercury	8150	8092½	7970	7955.4	9.3128399
Venus	501	517	504.985	498	7.8378910
The Sun	1800	169	1691.90	1681.395	8.2253628
Mars	14115.5	14155	14170	14183.7	8.9688921
Jupiter	25074	2506	25078.6	25013.3	8.6819346
Saturn	54143.5	5432	54381.4	53640.42	8.7499109
Herſchel				90804	8.6774873

The following table of excentricities in parts of the major axis is taken from the "Syſtem of the World," by La Place.

Mercury	-	0.205513
Venus	-	0.006885
Earth	-	0.016814
Mars	-	0.093808
Jupiter	-	0.048877
Saturn	-	0.056223
Uranus	-	0.046683

The ſecular variation of theſe numbers is as follows: (the ſign — indicates a diminution.)

Mercury	-	+ 0.000003369
Venus	-	— 0.000062905
The Earth	-	— 0.000045572
Mars	-	+ 0.000090685
Jupiter	-	+ 0.000134254
Saturn	-	— 0.000261553
Uranus	-	— 0.000026228

Excentricity, *biſection of.* The biſection of the excentricity is a curious principle aſſumed by Ptolemy, and the ancient aſtronomers, to explain the irregularities of the planetary motions. It is thus deſcribed by Dr. Small.

The inequalities of the planets were ſo various and intricate, that the explications of them were for a long time extremely imperfect, and ſo partial, that no Grecian aſtronomer before Ptolemy had ſuppoſed it practicable to give a compleat theory of all. In the more ancient times the explications of them appear to have been made by orbits concentric to the earth, and charged with epicycles: but, as Ptolemy had found no method of repreſenting the ſecond inequalities, except by means of epicycles, ſo, to avoid the perplexity occaſioned by the multiplication of them, he gave the preference to an excentric orbit for the repreſentation of the firſt; and, by the ſuperior ſimplicity of the repreſentation, the authority of the excentric theory was for many centuries eſtabliſhed. With reſpect to thoſe firſt inequalities, at leaſt of the ſuperior planets, it appears to have been originally ſuppoſed, that they might be ſufficiently accounted for by the more ſimple ſolar hypotheſis. For, if the planet, in conſequence of its ſecond inequalities, be repreſented as moving in the circumference *a b c* (*fig.* 111) of an epicycle, the centre A L P Q, of this epicycle will repreſent the places which it would occupy, if it were diveſted of all ſecond inequality: and it was thought a ſufficient explication of the firſt inequality, to ſuppoſe that this centre moved equally round Z, the centre of the orbit, and conſequently inequably round O, the centre of the earth. But when, according to Kepler's conjectures on this ſubject, they endeavoured to account for the inequality of the latitudes in oppoſition, and of the digreſſions of the planets, eſpecially their greateſt digreſſions, from the point oppoſite to the ſun, by variations of their diſtances from O, it appeared that the point Z, round which the planet moved equably, could not be the ſame with the centre of the orbit; for, both the latitudes, and alſo the angles *a* O *c*, *d* O *f*, which the epicycle ſubtended at the centre of the earth, were found to be greater at the apogee, and leſs at the perigee than the limits of the excentric A L P Q permitted; and that, conſequently, the centre of the orbit occupied a place nearer than Z to the centre of the earth. It was therefore a matter of much greater difficulty to form an hypotheſis for the motions of the planets, than for thoſe of the ſun: for, if their firſt inequalities required one determined excentricity, or diſtance between the centre of uniform motion and the centre of the earth, the variations of their latitudes, and of their ſecond inequalities, ſhewed that this was not the excentricity of the orbit in which the epicycle moved, and that this orbit evidently required another. In what proportion the diſtance Z O between the centre of uniform motion and the centre of the earth ought to be divided by the centre of the orbit, appears to have been for a long time a matter of much uncertainty. But Ptolemy tells us that, on applying himſelf to inveſtigate the meaſure of the approach of the centre of the epicycle, within the circle A L P O at the apogee, and its conſequent withdrawing from it beyond the perigee, he found, by multiplied obſervations, that the centre of the orbit lay preciſely in the middle, between Z the centre of uniform motion, and O the centre of the earth. This is the famous principle, known by the name of the biſection of the excentricity: and, as Ptolemy gives no account of the means by which it was diſcovered, nor of the obſervations from which it was inferred, his aſſuming it has juſtly excited the wonder of all aſtronomers. The greater part believed him to have aſſumed it merely from conjecture, and not to have derived it, as Kepler more generouſly ſuppoſed, from any obſervations; and there ſeems to be ſome reaſon for thinking that it came to him by tradition, from the more ancient aſtronomy of the Eaſt.

EXCEPTIO, in the *Roman Law.* See Pleading.

EXCEPTION, ſomething reſerved, or ſet aſide, and not included in a rule.

It is become proverbial, that there is no rule without an exception; intimating, that it is impoſſible to comprehend all the particular caſes under one and the ſame maxim. But it is dangerous following the exception preferably to the rule.

Exception, in *Law*, is a ſtop or ſtay to an action.

The term is uſed indifferently, both in the civil and common law; and in each exceptions are divided into *dilatory* and *peremptory*.

In law proceedings, exception is a denial of a matter alleged in bar to the action; and in chancery it is that which is alleged againſt the ſufficiency of an anſwer, &c. Exception, in a general ſenſe, includes all the kinds of defence, or vindication, which a perſon, againſt whom a proceſs is brought, makes uſe of to prevent or retard its effect.

The civilians reckon three kinds of exceptions; *viz. declinatory*, whereby the authority of the judge or court is diſallowed; *dilatory*, intended to defer or prevent the thing from coming to an iſſue; and *peremptory*, which are proper and pertinent allegations, founded on ſome preſumption that ſtands for the defendant; as want of age, or other quality, in the party; or other matter that may be decided, without entering into a full diſcuſſion of the merits of the cauſe.

Exception *to evidence*, is where a demurrer is offered in any civil cauſe, on account of the inſufficiency of the evidence given, and the court does not agree to it; in which caſe the court or judge are required to ſeal a bill of exceptions, by ſtat. Weſtm. 2. 13 Edw. I. cap. 31. which is in the nature of an appeal, examined in the next immediate ſuperior court, upon a writ of error after judgment given in the court below. See Demurrer, and Evidence.

Exception, *in deeds and writings*, is the ſaving of a particular thing out of a general one granted by deed, as a room, ſhop, or cellar, out of a houſe; a field, or timber-trees, out of land, &c. Exceptions of this kind muſt not croſs the grant, nor be repugnant to it, or elſe they are void of courſe; yet there may be a kind of exception, or ſaving out of an exception, ſo as to make a thing as if never excepted; as where a leaſe is made of a rectory, excepting the parſonage-houſe, ſaving to the leſſee a chamber, this ſhall paſs by the leaſe.

EXCEPTIVE Conjunction. See Conjunction.

Exceptive *propoſitions*, are thoſe wherein ſomething is affirmed of a whole ſubject, abating ſome one of the parts thereof, which is *excepted* by a particle, thence called an exceptive particle, or particle of exception.

Thus, "All the ſects of the ancient philoſophers, except the Platoniſts, held God to be corporeal. Covetouſneſs is inexcuſable in reſpect of every thing, but time."

EXCESS is diſtinguiſhed into *natural* and *moral*: the firſt, is a part whereby one quantity is greater than another. Thus, we ſay, this line is longer than that; but the exceſs is inconſiderable.

The latter is an intemperance, or going beyond the juſt bounds and meaſures preſcribed for any thing. Thus, we ſay, exceſs in wine, women, &c. is prejudicial to the health.

EXCESSIVE, in *Muſic*, is uſed as a prefix to denote the exceſs of certain tempered intervals above the true intervals of the ſame name; it is generally oppoſed to defective, *viz.* when there is a deficiency to the ſame extent as there is here an exceſs; but their uſe is not limited to any certain quantity of exceſs or defect, they being ſometimes applied in conjunction with or to repreſent the diaſchiſm, ſometimes with enharmonic dieſis, at others with minimum ſemitone, &c.; whereas the prefixes, redundant and deficient, are uſed only with the major comma, and hence the word comma is ſometimes omitted; and in like manner the prefixes ſuperfluous and diminiſhed are confined to the minor ſemitone, which laſt word is therefore ſometimes omitted in naming the claſs of intervals, which are increaſed or leſſened by a minor ſemitone.

EXCHANGE, in *Commerce*, and *Political Economy*, is the act of paying or receiving money in one country for its equivalent in the money of another country, by means of bills of exchange.

This ſcience, therefore, comprehends both the reduction of monies, and the negociation of bills: it determines the relative value of the currencies of all nations, and ſhews how foreign debts are diſcharged, loans and ſubſidies paid, and other remittances made from one place to another, without the riſk or expence of tranſporting ſpecie.

This important ſubject may be conſidered under the five following heads, namely:

1. Bills of exchange.—2. Par of exchange.—3. Courſe of exchange.—4. Monies of exchange.—5. Arbitration of exchange.

Bills of exchange.—A bill of exchange is a written order for the payment of a certain ſum of money at an appointed time. It is a mercantile contract in which four perſons are moſtly concerned, *viz.* 1. The *drawer*, who receives the value. 2. His debtor in a diſtant place, upon whom the bill is drawn, who is called the *drawee*, and who is to accept and pay it. 3. The perſon who gives value for the bill, and who is called the *buyer* and *remitter*; and, 4. The perſon to whom it is ordered to be paid, who is called the *payee*, and who may, by indorſement, paſs it to any other holder.

Moſt mercantile payments are made in bills of exchange, which, until due, generally paſs from hand to hand, like any other circulating medium. The laws of all trading nations afford the moſt ready and effectual means of enforcing the payment of bills, and hence that credit which they ſo univerſally obtain, and which greatly facilitates the operations of commerce.—For the laws, cuſtoms, and regulations of bills of exchange, ſee Bill of *exchange*, and *Mercantile* Law. See alſo Agio, Usance, and Days *of Grace*.

Bills are diſtinguiſhed into inland and foreign, according as they are made payable in the country where they are drawn, or in a foreign country. Their functions, however, are ſimilar in both caſes, and therefore in explaining the theory of exchange, we ſhall begin with the operations of inland bills as the moſt ſimple and familiar.

Suppoſe A. of London is creditor to B. of Edinburgh 100*l.* and C. of London debtor to D. of Edinburgh 100*l.* theſe two debts may be diſcharged by the operation of one bill: thus, A. draws on B. and ſells his bill to C. who remits it to D. and the latter receives the amount from B. when due. Here, by a transfer of claims, the London debtor pays the London creditor, and the Edinburgh debtor the Edinburgh creditor.

By the foregoing example it appears that reciprocal and equal debts due between two places, may be diſcharged without any caſh remittance, and it may be ſuppoſed that ſuch an operation is of equal convenience to the parties concerned, in both places; but when debts are unequal, the advantage muſt be likewiſe different, as the obligation of remittance is no longer mutual; for the debtor place muſt pay its balance either by ſending caſh or bills; and as the latter mode is generally preferred for ſeveral reaſons, an increaſed demand for ſuch bills muſt be the conſequence; and this enhances their price, as it would that of any other ſaleable article.

This is the plain principle of exchange which is conſtantly exemplified in the premium paid for inland bills on London; for this city, being the grand emporium of commerce that furniſhes moſt other places of the kingdom with foreign merchandize, and being alſo the reſidence of numerous

numerous landlords whoſe rents muſt be remitted to them from the country, it has generally a large balance of debt in its favour, a great part of which muſt be ſent in bills; this creates a demand, and conſequently a premium which is moſtly commuted for time; thus, if A. of London be creditor to B. of Edinburgh 200*l.* and C. of London debtor to D. of Edinburgh only 100*l.* the balance of 100*l.* againſt Edinburgh cannot be cancelled by a transfer of claims, but muſt, we will ſuppoſe, be remitted by a bill, which can be only obtained at a certain number of days after date. The moſt general term for bills from Edinburgh on London is 40 days, and the intereſt for this time is about ½ *per cent.* The number of days here is called the exchange, which has been known to vary conſiderably according to the balance of debt, or the plenty or ſcarcity of bills. A ſimilar premium or date is allowed for bills from all other places of Great Britain on the capital, but bills at ſight on any of thoſe places may be generally had in London without any premium whatever.

Although the principle of foreign exchange is the ſame as that of inland, yet the former is more complicated in its operations than the latter, owing to the denominations of money not being the ſame. This cauſes a difference in the mode of paying the premium for bills; in which, however, the date is taken into conſideration as well as the comparative rates at which the monies are valued.

In foreign exchange one place always gives another a fixed ſum or piece of money for a variable price, which fluctuates according to the balance of debt, as before ſtated: the former is called the certain price, and the latter the uncertain price. Thus London is ſaid to give to Paris the certain for the uncertain; that is, the pound ſterling for a variable number of francs; and to give to Spain the uncertain for the certain; that is, a variable number of pence ſterling for the dollar of exchange.

Whatever the uncertain price is, at any time, is called the courſe of exchange. Now ſuppoſe Paris gives London 25 francs for the pound ſterling, and that this ſum is found to contain the ſame quantity of pure ſilver as 20 ſhillings, then the exchange is ſaid to be at par; but if France ſhould give a higher price, it is ſaid to be in favour of London, and *vice verſâ.* This is the common mode of judging whether the exchange be favourable or unfavourable to a place, though it is not always the correct method, nor that which merchants generally act upon. But before we enter into any further explanation of the courſe of exchange, or the cauſes of its fluctuation, it will be neceſſary to explain more fully what is to be underſtood by the par of exchange, a ſubject on which there is ſome difference of opinion, even among writers of the firſt authority.

Par of Exchange.

The par of exchange may be conſidered under two general heads; namely, the *intrinſic par,* and the *commercial par,* each of which admits of ſubordinate diviſions and diſtinctions.

The intrinſic par of exchange is the value of the money of one country compared with that of another, with reſpect both to weight and fineneſs. Thus, two ſums of different countries are intrinſically at par when they contain an equal quantity of the ſame kind of pure metal, ſeparated from its alloy, which is always deemed of no value. See Coin.

There ſhould be two intrinſic pars, the one between gold coins, and the other betweeen ſilver coins; and hence the intrinſic par of exchange can be only determined with accuracy between places which pay their bills in the ſame kind of metal, as between England and Portugal, that pay in gold coin; or between France and Spain, that pay in ſilver coin, for the relative value between theſe metals is ſcarcely ever the ſame in any two countries.

It may be even obſerved, that the value of the ſame metal differs conſiderably in different countries, and therefore this intrinſic par of exchange cannot be always conſidered as a true equality in the value of monies; thus in the caſe of France and Spain, where the latter country ſupplies the former with the materials of her ſilver coinage, ſilver muſt be moſt valuable in France, and the difference ſhould be equivalent to the charges attending the removal, ſuch as the duty paid (in time of peace) to the Spaniſh government, for the exportation of dollars, the expences of carriage, inſurance, commiſſion, intereſt, &c. all of which amount to nearly 7 *per cent.*

A ſimilar computation might be made between gold in England and in Portugal, as the latter country ſupplies the former with the materials of her gold coinage.

But where one country pays its bills in gold, and another in ſilver, no intrinſic par of exchange whatever can be permanently eſtabliſhed. An equivalency can be only aſcertained by valuing as merchandize the gold of one place, and the ſilver of the other, according to the market price of the day; but this is the commercial par, which ſhall be more fully explained below.

In aſcertaining the intrinſic par between coins of the ſame metal, a queſtion occurs, whether the computation ſhould be made according to the mint regulations of the reſpective countries where the monies are ſtruck, or according to actual aſſays. The former is the moſt general method, though the latter is certainly the moſt correct; for while ſome governments make coins according to their full ſtandard, as in England, others take advantage of the allowance for remedy, and ſometimes make it a ſource of conſiderable emolument.

There are ſome countries with which no par of exchange, either intrinſic or commercial, can be permanently fixed. Theſe are ſuch as pay their bills in paper, which muſt have a fluctuating and precarious value. Even the bank money of Amſterdam and Hamburgh comes in a certain degree within this deſcription, as it bears a fluctuating agio againſt currency.

The *commercial par* is the comparative value of the monies of different countries, according to the weight, fineneſs, and market price of the metals. This is the par which merchants generally conſider of importance in their exchange ſpeculations, and we cannot define it better than in the following paſſage, taken from the Minutes of the Committee of the Houſe of Commons, appointed in 1804, to enquire into the ſtate of exchange between Ireland and England. Several of the moſt intelligent merchants of both countries were examined on the occaſion, and their evidence produced much new and practical information.

In the examination of Benjamin Winthrop, eſq. governor of the bank of England, an intereſting enquiry and inveſtigation took place reſpecting the par of exchange, from which the following appropriate queſtion and anſwer are extracted.

Queſtion.—"When a ſum of Hamburgh currency, which will buy a pound of bullion of given purity in the market of Hamburgh, can purchaſe a bill for a ſum of Engliſh currency, which will buy a pound of bullion of the ſame ſtandard in the Engliſh market, is not then the exchange at par between thoſe two countries?"

Anſwer.—"I confeſs it does appear to be a complete par of exchange."

This par of exchange is variouſly denominated by different writers on political economy; thus it is called the *current*, the *momentary*, the *political*, and the *eventual par*; and though each of theſe terms ſeems to convey a correct idea of the ſubject, yet we have adopted the word *commercial* as equally appropriate and more generally underſtood.

Some notice might be here taken of what is called a *monetary par*, in which an allowance is made for ſeignorage and mint expences, and alſo of a *common* or *eſtimate par*, which generally differs from the true one; thus the pound ſterling of England is eſtimated at 11 guilders current of Holland; but ſuch definitions are of little utility in the illuſtration of exchange.

The following opinion on the par of exchange ſeems to deſerve quotation. It is tranſlated from the preface of a moſt elaborate work, entitled "Dictionaire des Arbitrages," by Francois Corbaux, publiſhed at Paris in 1802.

"Without dwelling any longer," ſays this author, "on the arbitrary notions which have been formed of the par of exchange, and without ſeeking to adopt new ones, which might be rendered very numerous, we ſhall conclude by obſerving, that although the intrinſic or pretended real par is made the foundation and principal element in the determination of the price of exchange, yet not being the ſame in the gold as in the ſilver coins, the pars of theſe two metals ſhould be kept totally diſtinct; and that beſides, as neither of them finds any direct application in the common courſe of exchange affairs, it is through ignorance that ſo much importance has been attached to them, and that they have been conſidered as the moſt correct expreſſion of the relative value of the monies of two countries. In ſhort to ſeek for a true and rational par is to ſuppoſe what cannot exiſt, that is, the fixing of different principles and elements which are ſubject to continual variation, and, after all, if this could be accompliſhed, it would preſent no object of real utility."

However well-founded the opinion of Monſieur Corbaux may be, we think it muſt be at leaſt ſatisfactory to merchants to underſtand the intrinſic par of exchange, and therefore we ſhall give new tables of it at the concluſion of the preſent article, computed both in gold and ſilver, with rules and examples for performing all ſuch calculations; and ſhall now proceed to the explanation of the courſe of exchange, which is a ſubject of great importance, whether we conſider it in a commercial or political point of view.

Courſe of Exchange.

The courſe of exchange is the current price or proportion between the monies of two places; which is always fluctuating according to circumſtances.

When merchants have occaſion to draw or remit foreign bills, they meet upon the Royal Exchange, where this kind of buſineſs in London muſt be tranſacted. The market is conſtantly attended by exchange-brokers, to whom the wants of the parties who wiſh to buy or ſell bills are privately communicated. Theſe brokers, whoſe confidential ſituation demands ſtrict impartiality, bring parties together; and ſettle the courſe of exchange for the day, as ſoon as they learn how the market ſtands with reſpect to the number of drawers and remitters. The commiſſion for this buſineſs throughout Europe, is one *per mille* (or thouſand) which is equally paid by the buyers and ſellers of bills.

When the courſe of exchange riſes above par againſt any country, it is then concluded that the balance of trade is againſt that place. Now, if England ſhould import from France goods to the value of 100,000 *l.*, and export only to the value of 80,000 *l.*, it may coſt England 120,000 *l.* to pay the whole debt, if it ſhould be publicly known that ſo great a balance exiſts, and therefore ſecrecy is of peculiar importance in this kind of buſineſs.

The fluctuations of exchange are moſtly greater or leſs according to the known amount of the balance, and the expence and difficulty of conveying ſpecie. By the expence of ſuch conveyance is meant the carriage and inſurance, and by the difficulty the hazard of evading thoſe prohibitory regulations which, in moſt countries, impede the exportation of coin; and ſo powerful is the operation of theſe cauſes, that the exchange is ſometimes very high, or unequal, even between neighbouring countries, affording room for very profitable ſpeculations for thoſe merchants who circulate bills in the way of arbitration of exchange.

An unfavourable ſtate of the exchange with a country furniſhes a motive for exporting commodities to it. The merchant under theſe circumſtances can afford to ſell his goods as much cheaper as the premium which he receives for his bill amounts to. Hence the courſe of exchange tends to correct itſelf, and, in peace, it ſeldom continues, for any length of time, more unfavourable than the amount of the expences which might be incurred by tranſporting bullion to pay the balance which is to be remitted; for bullion may be conſidered the univerſal currency of merchants, though it is not always of ready or immediate application.

Although an unfavourable balance of trade has been generally conſidered an invariable cauſe of an unfavourable courſe of exchange, yet recent experience has ſhewn that this is not always the caſe. Thus, in the inveſtigation already alluded to, which took place in the Houſe of Commons relating to the exchange between England and Ireland, it was demonſtrated that the balance of trade was in favour of Ireland, while the courſe of exchange was highly unfavourable; it was, however, ſhewn in ſubſequent publications on the ſubject by Meſſrs. Parnell and Forſter, that though the balance of trade was in favour of Ireland, the balance of debt was unfavourable, or, in other words, the balance of remittance, on account of the number of Iriſh abſentees reſident in England; but perhaps the political ſtate of the country was the chief cauſe.

In time of war the fluctuations of the courſe of exchange are ſometimes very great, particularly where large remittances are to be made in the way of foreign loans or ſubſidies. The exchange is likewiſe lowered by any debaſement of the coin of a country, or by the depreciation of any other circulating medium. Even an exceſs of currency has the effect of turning the rate of exchange againſt that place where it prevails, as the exceſs raiſes the price of all commodities beyond their value in thoſe places where no ſuch redundancy exiſts. It may, however, be obſerved, that the nature of exchange operates to effect the general diſtribution of the ſurplus ſpecie, and to maintain the level of money throughout the commercial world. In ſhort, in all caſes, the exchange tends to an equilibrium.

Although the depreciation of the circulating medium of a country raiſes the courſe of exchange againſt it, the circumſtance is not always a diſadvantage. Thus, before the reformation of our ſilver coinage, in the reign of William the Third, the exchange between England and Holland, computed by the ſtandard of their reſpective mints, was 25 *per cent.* againſt England, but the current coin of England was more than 25 *per cent.* below its nominal or ſtandard value; and therefore the exchange was virtually in favour of England, according to the ſtatement of Dr. Adam Smith.

It may be further obſerved, that the wealth of a country will ſometimes raiſe the courſe of exchange againſt it, on account of its importations of luxuries from abroad. Rich countries are likewiſe liable to have the courſe of exchange turned againſt them by the ſubſidies which they may have to remit to leſs opulent ſtates, as before noticed.

Thus in 1793, the trade between Holland and England was completely open; and yet the courſe of exchange was 10 or 12 *per cent.* againſt Amſterdam, owing probably to the balance of trade being ſo much in favour of London. But, in 1794, when England undertook to ſubſidize Pruſſia, large remittances of bills were made through Amſterdam, which cauſed an immediate fall in the courſe of exchange between that place and London, even below par: and therefore at ſubſequent periods of the war, it has been thought prudent by the Engliſh government to export ſpecie on ſuch occaſions, rather than to turn the courſe of exchange againſt London by the operation of remitting large ſubſidies in bills. During the preſent war between France and Auſtria (1809) the latter power has been ſubſidized by the Engliſh government, which has been chiefly done in bills, and this has tended to raiſe the exchange againſt England, in the places where thoſe bills were negociated. But the cauſe which has operated more powerfully to produce this effect is the great exportation of goods to England, from Germany, France, and Holland, without any adequate importation of Engliſh merchandize. Hence the exchange with London has been for ſome time greatly in favour of thoſe places, while between London and moſt of the other parts of Europe it has continued nearly at par.

From what has been ſaid reſpecting the cauſes, both commercial and political, which produce the fluctuations of exchange, and which frequently counteract each other, the following ſimple concluſion may be drawn; that whatever produces a demand for bills on any place tends to enhance their value, and therefore the courſe of exchange riſes and falls according to the proportion which exiſts between the plenty and ſcarcity of bills, that is, between the demand and the ſupply.

Monies of Exchange.

The following tables contain the monies of exchange of the principal trading places of Europe, in all their varieties and combinations. Explanations are alſo given of the quotations or liſts of the courſes of exchange, which are tranſmitted from one country to another for the government and advice of merchants. Theſe quotations ſeldom give more than the figures of the uncertain prices, omitting the denominations of money and the certain prices, all of which are here explained.

Note.—In all the uncertain prices the words *more or leſs* are to be underſtood.

AMSTERDAM.

Monies of Exchange.

Exchanges are computed in florins, ſtivers, and pennings; or in pounds, ſhillings, and pence Flemiſh.

16 Pennings = 1 Stiver
20 Stivers = 1 Florin or guilder
2 Grotes or pence Flemiſh = 1 Stiver
12 Grotes or 6 ſtivers = 1 Shilling Flemiſh
20 Shillings Flemiſh, or 6 florins = 1 Pound Flemiſh.

There are two ſorts of money in Holland; namely, *banco* and *currency:* banco generally bears a premium againſt currency of 4 or 5 *per cent.* which is called *agio.*

Quotation explained.

Amſterdam gives to	Uncertain prices.		Certain prices.
London	34 ſhillings 8 grotes Flemiſh	for	1 Pound ſterling
France	54 Grotes Flemiſh	—	3 Francs
Spain	99 Ditto	—	1 Ducat of exch.
Portugal	44 Ditto	—	1 Old cruſade
Genoa	86 Ditto	—	1 Pezza of 5¾ lire
Leghorn	92 Ditto	—	1 Pezza of 8 reals
Hamburgh	34 Stivers	—	2 Marks
Vienna	20 Ditto	—	1 Rixdollar
receives from			
Antwerp	104 Florins	—	100 Florins
Breſlau	144 Rixdollars	—	100 Rixdollars
Venice	96 Soldi piccoli	—	1 Florin

N. B. The exchanges of Amſterdam are always tranſacted in banco, unleſs otherwiſe expreſſed.

AUGSBURG.

Monies of Exchange.

Exchanges are computed in florins and creutzers, and alſo in rixdollars and creutzers.

60 Creutzers = 1 Florin
1½ Florin or 90 creutzers = 1 Rixdollar of account.

Two ſorts of money are uſed here; giro, that is, money of exchange, and currency.

100 Florins of exchange = 127 Florins current.

Quotation explained.

Augſburg gives to	Uncertain prices.		Certain prices.
Amſterdam	113 Rixdollars of exchange	for	100 Rixdollars
Hamburgh	118 Ditto Ditto	—	100 Ditto
Francfort	102 Rixdollars cur.	—	100 Ditto
Leipſic	99 Ditto Ditto	—	100 Ditto
London	10 Florins 45 creutzers	—	1 Pound ſterling
Paris	120 Florins current	—	300 Francs
Nuremberg	101 Florins Ditto	—	100 Florins
receives from			
Genoa	62 Soldi fuori banco	—	1 Florin
Leghorn	57 Soldi moneta buona	—	1 Ditto
Vienna	128 Florins	—	100 Ditto.

BERLIN.

Monies of Exchange.

Exchanges are computed in rixdollars, good groſchen, and pfenings currency.

12 Pfenings = 1 Good groſche
24 Good groſchen = 1 Rixdollar of account.

Quotation explained.

Berlin gives to	Uncertain prices.		Certain prices.
Amſterdam	154 Rixdollars	for	100 Rixdollars
Breſlau	100½ Ditto	—	100 Ditto
Hamburgh	158 Ditto	—	100 Ditto
Konigſberg	100½ Ditto	—	100 Ditto
Francfort	105 Ditto	—	100 Ditto
Leipſic	104 Ditto	—	100 Ditto
London	6½ Ditto 12 groſchen	—	1 Pound ſterling
Paris	83 Rixdollars	—	300 Francs
Augſburg	106 Ditto	—	100 Rixdollars
Vienna	60 Ditto	—	100 Ditto.

Bologna. See Rome.

Bremen.

Monies of Exchange.

Exchanges are computed in rixdollars, grotes, and ſwares

5 Swares = 1 Grote
72 Grotes = 1 Rixdollar of account.

Quotation explained.

Bremen gives to	Uncertain prices.		Certain prices.
Amſterdam	143 Rixdollars	for	100 Rixdollars
Hamburgh	142 Ditto	—	100 Ditto
Francfort	110 Ditto	—	100 Ditto
Leipſic	104 Ditto	—	100 Ditto
London	605 Ditto	—	100 Pounds ſterling
Nuremberg	104 Ditto	—	100 Rixdollars
Paris	20 Grotes	—	1 Franc
Vienna	90 Rixdollars	—	100 Rixdollars.

Breslau. See Berlin.

Cadiz.

Monies of Exchange.

Exchanges are computed in dollars, reals, and maravedis of old plate; alſo in ducats of exchange, and in dobloons of plate, or piſtoles of exchange.

34 Maravedis = 1 Real
8 Reals = 1 Dollar of plate
375 Maravedis of plate = 1 Ducat of exchange
4 Dollars of plate = 1 Piſtole of exchange.

N. B. Vellon, the current money of Spain, is to old plate as 17 to 32; that is,

32 Reals or maravedis vellon = 17 Reals or maravedis of old plate.

Quotation explained.

Cadiz gives to	Uncertain prices.		Certain prices.
Genoa	121 Dollars of plate	for	100 Pezze of $5\frac{3}{4}$ lire
Leghorn	130 Ditto	—	100 Pezze of 8 reals
Naples	290 Maravedis of plate	—	1 Ducat regno
receives from			
Amſterdam	97 Grotes Flemiſh	—	1 Ducat of exch.
London	42 Pence ſterling	—	1 Dollar of plate
Paris	78 Sous tournois	—	1 Ditto
Hamburgh	90 Grotes Flemiſh	—	1 Ducat of exch.
Liſbon	2470 Rees	—	1 Dobloon of plate

Constantinople.

Monies of Exchange.

Exchanges are computed in piaſtres, paras, and aſpers; or in piaſtres and aſpers.

3 Aſpers = 1 Para
40 Paras or 120 aſpers = 1 Piaſtre or dollar.

Quotation explained.

Conſtantinople gives to	Uncertain prices.		Certain prices.
London	17 Piaſtres	for	1 Pound ſterling
Vienna	50 Paras	—	1 Florin
Leghorn	145 Ditto	—	1 Pezza of 8 reals
Genoa	24 Ditto	—	1 Lirafuori banco
Amſterdam	65 Ditto	—	1 Florin current
Paris	200 Piaſtres	for	300 Francs
Venice	360 Paras	—	1 Sequin of 22 lire
receives from			
Marſeilles	1 Franc, 50 centimes	—	1 Piaſtre
Hamburgh	25 Grotes Flemiſh	—	1 Ditto
Smyrna	110 Piaſtres	—	100 Ditto.

Copenhagen.

Monies of Exchange.

Exchanges are computed in rixdollars, marks, and ſkillings Daniſh; and ſometimes in rixdollars, marks, and ſkillings lubs or Hamburgh. Pfenings are alſo ſometimes reckoned.

12 Pfenings = 1 Skilling
16 Skillings = 1 Mark
6 Marks Daniſh, or 3 marks lubs = 1 Rixdollar
2 Marks or ſkillings Daniſh = 1 Mark or ſkilling lubs.

Quotation explained.

Copenhagen gives to	Uncertain prices.		Certain prices.

Hamburgh	149 Ditto	—	100 Ditto
London	6 Rixdollars 30 ſhillings	—	1 Pound ſterling
Paris	25 Skillings Daniſh	—	1 Franc.

Dantzic.

Monies of Exchange.

Exchanges are computed in florins, groſchen, and pfenings.

18 Pfenings = 1 Groſche
30 Groſchen = 1 Florin or gulden
3 Florins = 1 Rixdollar.

Quotation explained.

Dantzic gives to	Uncertain prices.		Certain prices.
Amſterdam	372 Groſchen	for	1 Pound Flemiſh
Hamburgh	169 Ditto	—	1 Rixdollar ſpecie
London	24 Florins	—	1 Pound ſterling
Paris	110 Rixdollars	—	300 Francs
Francfort	105 Groſchen	—	1 Rixdollar.
Leipſic	125 Rixdollars	—	100 Ditto.

Florence. See Leghorn.

Francfort.

Monies of Exchange.

Exchanges are computed in florins and creutzers; or in rixdollars and creutzers; alſo in florins and batzen.

4 Creutzers = 1 Batze
60 Creutzers, or 15 batzen = 1 Florin or gulden
90 Creutzers, or $1\frac{1}{2}$ florin = 1 Rixdollar of account.

Quotation explained.

Francfort gives to	Uncertain prices.		Certain prices.
Amſterdam	140 Rixdollars	for	100 Rixdollars current
Hamburgh	150 Ditto	—	100 Ditto banco Francfort

Francfort gives to	Uncertain prices.		Certain prices.
Augſburg	101 Rixdollars	for	100 Rixdollars banco
Vienna	60 Florins	—	100 Florins
France	79 Rixdollars	—	300 Livres
Leipſic	$100\frac{1}{2}$ Ditto	—	100 Rixdollars in louis d'or
Bremen	108 Ditto	—	100 Ditto
Baſil	101 Ditto	—	100 Ditto in new ecus.

GENEVA.

Monies of Exchange.

Exchanges are computed in livres, ſous, and deniers current; and in ecus, livres, &c.

12 Deniers = 1 Sou or ſol
20 Sous = 1 Livre
3 Livres = 1 Ecu.

Quotation explained.

Geneva gives to	Uncertain prices,		Certain prices.

Leghorn	104 Ecus	—	100 Pezze of 8 reals
Genoa	95 Ditto	—	100 Pezze of $5\frac{3}{4}$ lire
Milan	98 Ditto	—	640 Current lire
Spain	44 Sous	—	1 Dollar of plate
receives from			
France	166 Francs	—	100 Livres
London	49 Pence ſterling	—	1 Ecu
Amſterdam	89 Grotes Flemiſh	—	1 Ditto
Augſburg	127 Rixdollars current	—	100 Ditto
Baſil	168 Livres tournois	—	100 Livres
Turin	84 Soldi	—	1 Ecu.

GENOA.

Monies of Exchange.

Exchanges are computed in lire, ſoldi, and denari di lira; or in pezze, ſoldi, and denari di pezza; all in currency, called *fuori banco.*

12 Denari di lira = 1 Soldi di lira
20 Soldi di lira = 1 Lira
12 Denari di pezza = 1 Soldo di pezza
20 Soldi di pezza = 1 Pezza
$5\frac{3}{4}$ Lire = 1 Pezza
4 Lire 12 ſoldi = 1 Scudio di cambio, or crown of exchange
10 Lire 14 ſoldi = 1 Scudo d'oro marche, or gold crown.

Quotation explained.

Genoa gives to	Uncertain prices.		Certain prices.
Leghorn	124 Soldi di lira	for	1 Pezza of 8 reals
Rome	128 Ditto	—	1 Roman crown
Naples	103 Ditto	—	1 Ducat regno
Hamburgh	45 Ditto	—	1 Mark
Vienna	30 Ditto	—	1 Florin
Augſburg	62 Ditto	—	1 Ditto
receives from			
Venice	33 Soldi piccoli	—	1 Lira
Palermo	36 Grani	—	1 Ditto
Amſterdam	85 Grotes Flemiſh	—	1 Pezza
France	94 Sous in francs	—	1 Ditto
Genoa receives from	Uncertain prices.		Certain prices.
Spain	620 Maravedis of plate	for	1 Gold crown
Liſbon	718 Rees	—	1 Pezza
Milan	87 Soldi	—	4 Lire
London	48 Pence ſterling	—	1 Pezza

HAMBURGH.

Monies of Exchange.

Exchanges are computed in marks, ſchilling lubs, and pfenings; or in pounds, ſhillings, and pence Flemiſh; alſo in rixdollars, marks, &c.

12 Pfenings = 1 Schilling lubs
16 Schillings = 1 Mark
3 Marks = 1 Rixdollar
6 Pfenings = 1 Grote or penny Flemiſh
12 Grotes = 1 Shilling Flemiſh
20 Shillings Flemiſh = 1 Pound Flemiſh
Thus, 6 Schilling lubs = 1 Shilling Flemiſh
$7\frac{1}{2}$ Marks = 1 Pound Flemiſh.

There are two ſorts of money in Hamburgh, called *banco* and *currency*. Banco bears an agio or premium againſt currency, which is generally from 20 to 25 *per cent.*

Quotation explained.

Hamburgh gives to	Uncertain prices.		Certain prices.
London	33 Shillings 7 Grotes Flem.	for	1 Pound ſterling
France	26 Schilling lubs	—	3 Francs
Spain	91 Grotes Flemiſh	—	1 Ducat of exch.
Portugal	43 Ditto	—	1 Old cruſade
Genoa	80 Ditto	—	1 Pezza of $5\frac{3}{4}$ lire
Leghorn	86 Ditto	—	1 Pezza of 8 reals
Baſil	25 Schilling lubs	—	1 Ecu of 3 francs
receives from			
Amſterdam	33 Stivers	—	2 Marks
Breſlau	139 Rixdollars	—	100 Rixdollars
Copenhagen	149 Ditto	—	100 Ditto
Vienna	310 Florins	—	100 Ditto
Venice	82 Soldi piccoli	—	1 Mark.

N. B. The exchanges of Hamburgh are always tranſacted in banco, unleſs otherwiſe expreſſed.

LEGHORN.

Monies of Exchange.

Exchanges are computed in pezze, ſoldi, and denari di pezza; ſometimes in lire, ſoldi, and denari di lira, moneta buona.

12 Denari di pezza = 1 Soldo di pezza
20 Soldi di pezza = 1 Pezza of 8 reals
12 Denari di lira = 1 Soldo di lira
20 Soldi di lira = 1 Lira
$5\frac{3}{4}$ Lire, moneta buona = 1 Pezza of 8 reals.

Quotation explained.

Leghorn gives to	Uncertain prices.		Certain prices.
Vienna	30 Soldi moneta buona	for	1 Florin
Novi	186 Pezze	—	100 Scudi d'oro marche.

Leghorn receives from	Uncertain prices.		Certain prices.
Rome	128 Bajocchi	for	1 Pezza of 8 reals
Naples	118 Ducats regno	—	100 Ditto
Palermo	11 Tari 15 grani	—	1 Ditto
Genoa	125 Soldi fuori banco	—	1 Ditto
Milan	136 Soldi correnti	—	1 Ditto
Florence	124 Soldi	—	1 Ditto
Turin	93 Soldi	—	1 Ditto
Venice	$10\frac{1}{2}$ Lire piccole	—	1 Ditto

London	66 Pence ſterling	—	1 Milree
Amſterdam	45 Grotes Flemiſh	—	1 Old cruſade
Hamburgh	43 Ditto	—	1 Ditto.

MADRID.

Monies of Exchange. See CADIZ.

Quotation of Madrid on Paris explained.

Madrid receives from	Uncertain price.		Certain price.
Paris	15 Francs 40 centimes	for	1 Dobloon of plate.

The other exchanges of Madrid are ſimilar to thoſe of Cadiz.

MILAN.

Monies of Exchange.

Exchanges are computed in lire, ſoldi, and denari correnti or imperiali.

12 Denari = 1 Soldo
20 Soldi = 1 Lira
106 Lire or ſoldi imperiali = 150 Lire or ſoldi correnti
117 Soldi imperiali = 1 Scudo or crown.

Quotation explained.

Milan gives to	Uncertain prices.		Certain prices.
France	55 Soldi imperiali	for	3 Francs
Genoa	86 Soldi correnti	—	4 Lire fuori banco
Rome	138 Ditto	—	1 Roman crown
Leghorn	135 Ditto	—	1 Pezza of 8 reals
Augſburg	66 Ditto	—	1 Florin current
Venice	84 Ditto	—	1 Ducat current
Vienna	55 Ditto	—	1 Florin current
Amſterdam	57 Ditto	—	1 Florin banco
London	31 Lire correnti	—	1 Pound ſterling
Hamburgh	49 Soldi correnti	—	1 Mark.

NAPLES.

Monies of Exchange.

Exchanges are computed in ducats and grains, or in ducats, carlins, and grains.

10 Grains = 1 Carlin
10 Carlins or 100 grains = 1 Ducat regno.

Quotation explained.

Naples gives to	Uncertain prices.		Certain prices.
Leghorn	120 Ducats regno	for	100 Pezze
Amſterdam	54 Grains	—	1 Florin
Spain	85 Ditto	—	1 Dollar of plate
Rome	125 Ducats	—	100 Roman crowns
Hamburgh	45 Grains	—	1 Mark
Sicily	120 Ditto	—	1 Sicilian crown
receives from			
London	42 Pence ſterling	—	1 Ducat regno
Genoa	102 Soldi fuori banco	—	1 Ditto
Venice	9 Lire 15 ſoldi piccoli	—	1 Ditto
France	84 Sous in francs	—	1 Ditto
Liſbon	670 Rees		1 Ditto.

PALERMO.

Monies of Exchange.

Exchanges are computed in ounces, tari, and grains; and alſo in ſcudi, tari, and grains.

20 Grains = 1 Taro
30 Tari = 1 Ounce
12 Tari = 1 Scudo or crown;
Thus 5 Crowns = 2 Ounces.

Quotation explained.

Palermo gives to	Uncertain prices.		Certain prices.
Amſterdam	$5\frac{1}{2}$ Tari	for	1 Florin
Genoa	40 Grains	—	1 Lira fuori banco
Leghorn	$12\frac{1}{2}$ Tari	—	1 Pezza of 8 reals
Liſbon	$6\frac{1}{4}$ Tari	—	1 Old cruſade
London	60 Tari	—	1 Pound ſterling
Paris	50 Grains	—	1 Livre
Rome	$12\frac{1}{2}$ Tari	—	1 Roman crown
Spain	$8\frac{1}{2}$ Tari	—	1 Dollar of plate.
receives from			
Naples	120 Grains	—	1 Sicilian crown.

PARIS.

Monies of Exchange.

Exchanges are computed in francs and centimes; or in livres, ſous, and deniers tournois.

100 Centimes = 1 Franc
12 Deniers = 1 Sou or ſol
20 Sous = 1 Livre
80 Francs = 81 Livres
3 Livres or 3 francs = 1 Ecu of exchange.

The 5 franc piece is alſo ſometimes divided into 100 ſous, which are diſtinguiſhed by ſaying, 100, or ſo many ſous in francs.

Quotation explained.

Paris gives to	Uncertain prices.		Certain prices.
London	24 Francs	for	1 Pound ſterling
Hamburgh	185 Francs	—	100 Marks
Genoa	465 Centimes	—	1 Pezza of 5¾ lire
Leghorn	524 Centimes	—	1 Pezza of 8 reals
Spain	15 Francs 40 cent.	—	1 Dobloon of plate
Geneva	162 Francs	—	100 Livres current
Baſil	101 Livres	—	100 Livres
Augſburg	249 Centimes	—	1 Florin current
Vienna	160 Centimes	—	1 Florin
Naples	4 Francs 20 cent.	—	1 Ducat regno
receives from			
Amſterdam	54 Grotes Flemiſh	—	3 Francs
Frankfort	75 Rixdollars cur.	—	300 Ditto
Liſbon	460 Rees	—	3 Ditto
Milan	8 Livres 6 ſoldi	—	6 Ditto.

PETERSBURGH.

Monies of Exchange.

Exchanges are computed in rubles and copecks.

100 Copecks = 1 Ruble.

Quotation explained.

Peterſburgh gives to	Uncertain prices.		Certain prices.
Conſtantinople	50 Copecks	for	1 Piaſtre.
receives from			
London	28 Pence ſterling	—	1 Ruble
Amſterdam	25 Stivers	—	1 Ditto
Vienna	125 Creutzers	—	1 Ditto
Leipſic	17 Groſchen	—	1 Ditto
Paris	270 Centimes	—	1 Ditto

ROME.

Monies of Exchange.

Exchanges are computed in ſcudi moneta, and bajocchi; or in ſcudi di ſtampa d'oro, ſoldi and denari d'oro; quattrini and mezzi quattrini are alſo ſometimes reckoned.

2 Mezzi quattrini = 1 Quattrino
5 Quattrini = 1 Bajocco or Bolognino
100 Bajocchi = 1 Scudo moneta, or Roman crown
1523 Mezzi quattrini, or $152\frac{3}{10}$ bajocchi = 1 Scudo di ſtampa d'oro, or gold crown
12 Denari d'oro = 1 Soldo d'oro
20 Soldi d'oro = 1 Gold crown.

Quotation explained.

Rome gives to	Uncertain prices.		Certain prices.
Florence	84 Gold crowns	for	100 Gold crowns
Milan	81 Roman crowns	—	100 Scudi imperiali
Ancona	99 Ditto	—	100 Crowns
Bologna	98 Ditto	—	100 Ditto
Leghorn	98 Bajocchi	—	1 Pezza of 8 reals
Amſterdam	44 Ditto	—	1 Florin

Rome receives from	Certain prices.		Uncertain prices.
Naples	122 Ducats regno	for	100 Roman crowns
Venice	11 Lire 10 ſoldi piccoli	—	1 Ditto
Genoa	124 Soldi fuori banco	—	1 Ditto
Paris	105 Sous in francs	—	1 Ditto
London	51 Pence ſterling	—	1 Ditto

ROTTERDAM.

Monies of Exchange. See AMSTERDAM.

Quotation on London explained.

Rotterdam gives to	Uncertain price.		Certain price.
London	11 Florence current	for	1 Pound ſterling.

For the other exchanges of Rotterdam, ſee AMSTERDAM.

STOCKHOLM.

Monies of Exchange.

Exchanges are computed in rixdollars, ſkillings, and fenings.

12 Fenings or Oers = 1 Skilling
48 Skillings = 1 Rixdollar.

Quotation explained.

Stockholm gives to	Uncertain prices.		Certain prices.
Amſterdam	44 Skillings	for	1 Rixdollar
Copenhagen	36 Ditto	—	1 Ditto
Dantzic	9½ Ditto	—	1 Florin
Hamburgh	47 Ditto	—	1 Rixdollar
Leghorn	40 Ditto	—	1 Pezza of 8 reals
London	4½ Rixdollars	—	1 Pound ſterling
Paris	24 Skillings	—	1 Ecu of 3 livres
Spain	42 Ditto	—	1 Ducat of exch.

TRIESTE. See VIENNA.

TURIN.

Monies of Exchange.

Exchanges are computed in lire, ſoldi, and denari.

12 Denari = 1 Soldo
20 Soldi = 1 Lira

Quotation explained.

Turin gives to	Uncertain prices.		Certain prices.
Amſterdam	37 Soldi	for	1 Florin
Augſburg	42 Ditto	—	1 Ditto
Geneva	82 Ditto	—	3 Livres
Genoa	9 Lire 8 ſoldi	—	1 Sequin
Leghorn	86 Soldi	—	1 Pezza of 8 reals
London	19 Lire 10 ſoldi	—	1 Pound ſterling
Milan	92 Soldi	—	7½ Lire correnti
Paris	20 Lire	—	24 Francs
Rome	87 Soldi	—	1 Roman crown
Venice	94 Ditto	—	1 Ducat current.

VENICE.

Monies of Exchange.

Exchanges are computed in lire, ſoldi, and denari, moneta piccola; and alſo in ducats.

12 Denari = 1 Soldo
20 Soldi = 1 Lira
6 Lire 4 ſoldi = 1 Ducat current, or of account
8 Lire = 1 Ducat effective

Quotation explained.

Venice gives to	Uncertain prices.		Certain prices.
London	56 Lire piccole	for	1 Pound ſterling
Amſterdam	4 Lire 18 ſoldi ditto	—	1 Florin
Augſburg	4 Lire 16 ſoldi ditto	—	1 Ditto
Conſtantinople	3 Lire 6 ſoldi	—	1 Piaſtre
Paris	2 Lire 5 ſoldi	—	1 Franc
Genoa	38 Soldi	—	1 Lira fuori banco
Hamburgh	4 Lire 6 ſoldi	—	1 Mark
Leghorn	11 Lire 18 ſoldi	—	1 Pezza
Milan	34 Soldi	—	1 Lira corrente
Naples	9 Lire 18 ſoldi	—	1 Ducat regno
Vienna	4 Lire 8 ſoldi	—	1 Florin
Rome	12 Lire 10 ſoldi	—	1 Roman crown.

VIENNA.

Monies of Exchange.

Exchanges are computed in florins and creutzers, or in rixdollars and creutzers; pfenings are ſometimes uſed.

4 Pfenings = 1 Creutzer
60 Creutzers = 1 Florin
90 Creutzers, or 1½ florin = 1 Rixdollar of account.

Quotation explained.

Vienna gives to	Uncertain prices.		Certain prices.
Amſterdam	286 Rixdollars	for	100 Rixdollars current
Augſburg	202½ Ditto	—	100 Ditto
Hamburgh	300 Ditto	—	100 Ditto banco
London	19 Florins	—	1 Pound ſterling
Paris	47 Creutzers	—	1 Franc
Conſtantinople	112 Florins	—	1 Piaſtre
Venice	184 Ditto	—	500 Lire piccole
Prague	99½ Ditto	—	100 Florins
receives from			
Genoa	30 Soldi fuori banco	for	1 Florin
Leghorn	28 Soldi moneta buona	—	1 Ditto
Milan	33 Soldi correnti	—	1 Ditto.

AMERICA.

Monies of Exchange.

Exchanges are computed in dollars, dimes, and cents; and in ſome places in pounds, ſhillings, and pence currency.

10 Cents = 1 Dime
10 Dimes, or 100 cents = 1 Dollar,
12 Pence currency = 1 Shilling ditto
20 Shillings currency = 1 Pound ditto.

American Quotations explained.

New York gives to	Uncertain prices.		Certain prices.
London	177 Pounds currency	for	1 Pound ſterling
Amſterdam	42 Cents	—	1 Guilder
Hamburgh	35 Cents	—	1 Mark
Bremen	78 Cents	—	1 Rixdollar
receives from			
Paris	5 Francs 30 cent.	—	1 Dollar.

Philadelphia gives to	Uncertain prices.		Certain prices.
Amſterdam	43 Cents	for	1 Guilder
Hamburgh	35 Cents	—	1 Mark
receives from			
London	4*s.* 6*d.* ſterling *at par*	—	1 Dollar

Baltimore gives to	Uncertain prices.		Certain prices.
Amſterdam	40 Cents	for	1 Guilder
Hamburgh	33 Cents	—	1 Mark
London	101 Cents	—	4*s.* 6*d.* ſterling.

Theſe American quotations have been copied from a New York paper of March 1809. All the other quotations may be likewiſe relied on, having been taken from genuine and recent authorities.

LONDON.

Monies of Exchange.

Exchanges are computed in pounds, ſhillings, and pence ſterling; and farthings are ſometimes reckoned.

4 Farthings = 1 Penny
12 Pence = 1 Shilling
20 Shillings = 1 Pound.

Lloyd's Liſt explained.

London gives to	Uncertain prices.		Certain prices.
Madrid	42 Pence ſterling	for	1 Dollar of plate
Genoa	47½ Ditto	—	1 Pezza of 5¾ lire
Leghorn	51½ Ditto	—	1 Pezza of 8 reals
Liſbon	68 Ditto	—	1 Milree
Naples	42 Ditto	—	1 Ducat regno
Palermo	90 Ditto	—	1 Ounce
receives from			
Amſterdam	34 Shillings Flem.	—	1 Pound ſterling
Rotterdam	11 Florins current	—	1 Ditto
Hamburgh	33 Shillings Flem.	—	1 Ditto
Paris	23 Livres 10 ſous	—	1 Ditto
Venice	52 Lire piccole	—	1 Ditto
Dublin	10 per cent, that is, 110*l.* Iriſh	—	100 Ditto.

Examples for calculating the exchanges of London with the above places are here given; whence the method of computing the exchanges of other places one with another may be eaſily comprehended, as all operations of this kind may be performed by the Rule of Three Direct.

LONDON and AMSTERDAM.

Engliſh money is reduced to Dutch by ſaying; as 1*l.* ſterling is to the rate of exchange, ſo is the given ſum to the ſum ſought.

Reduce 782*l.* 12*s.* 6*d.* ſterling to Dutch money, exchange at 34 ſhillings and 8 pence Flemiſh *per* pound ſterling.

                              2643 Doll. 6 R. 14 M.
                              ----
```

But if the anſwer be required in vellon, the reals of plate ſhould be multiplied by 32 and divided by 17; thus,

```
                Reals.  Mar. plate.   Reals.  Mar. vel.
As 17 : 32 :: 21150      14     :   39812     18
```

Spaniſh money is reduced to Engliſh by reverſing the foregoing operation: thus,

```
     Doll.      d.        Doll. R. Mar.       £.  s. d.
As    1    :   35½   ::   2643  6  14    :   391  1 3
```

London and Leghorn.

Engliſh money is reduced to that of Leghorn by ſaying; as the rate of exchange is to 1 pezza, ſo is the given ſum to the ſum ſought.

Reduce 392*l*. 18*s*. 4¼*d*. ſterling to money of Leghorn; exchange at 50¼*d*. *per* pezza of 8 reals.

```
     d.     Pezza.      £.  s. d.       Pezze Sol. De.
As  50¼  :   1   ::   392 18 4¼    :   1876  12  5
     4               ×20×12×4
    ---             ----------
    201         201)377201(1876 Pez. 12 Sol. 5 Den.
    ---             201
                    --- &c.
```

Money of Leghorn is reduced to Engliſh by reverſing the foregoing operation; thus,

```
     Pezza     d.        Pezze Sol. Den.       £.  s. d.
As    1    :  50¼   ::   1876  12  5    :   392 18 4¼
```

London and Genoa.

Engliſh money is reduced to money of Genoa by an analogy ſimilar to the foregoing.

Reduce 239*l*. 11*s*. 3*d*. to money of Genoa; exchange at 45*d*. ſterling *per* pezza of 5¾ lire fuori banco.

```
     d.    Pezza       £.  s. d.       Pezza Sol. Den.
As   45  :   1   ::   239 11 3    :   1277  13   4
                      ×20×12
                   -----------
                45)57495(1277 Pezze 13 Soldi 4 Den.
                   45
                   --
                   124, &c.
```

But if the anſwer be required in lire, the ſum thus found ſhould be multiplied by 23, and divided by 4; thus,

Pez. Sol. D. di Pez. Lire Sol. D. di Lira
As 4 : 23 :: 1277 13 4 : 7346 11 8

Money of Genoa is reduced to Engliſh by reverſing the foregoing operation; thus

Lire Sol. D. di Lira Pez. Sol. D. di Pez.
As 23 : 4 :: 7346 11 8 : 1277 13 4

Pezza *d.* Pezze Sol. Den. £. *s.* *d.*
And as 1 : $50\frac{1}{4}$ :: 1277 13 4 : 239 11 3

LONDON and LISBON.

Engliſh money is reduced to Portugueſe by ſaying: as the rate of exchange is to 1 milree, ſo is the given ſum to the ſum ſought.

Reduce 218*l.* 8*s.* $5\frac{1}{4}$*d.* to Portugal money; exchange at $63\frac{3}{8}$*d.* ſterling *per* milree.

d. Milree £. *s.* *d.* Mil. Rees
As $63\frac{3}{8}$: 1 :: 218 8 $5\frac{1}{4}$: 827 160
8 × 20 × 12 × 8

507 507)419370(827,160
4056
&c.

Portugal money is reduced to Engliſh by reverſing the foregoing operation; thus,

Milree *d.* Mil. Rees £. *s.* *d.*
As 1 : $63\frac{3}{8}$ :: 827 160 : 218 8 $5\frac{1}{4}$

LONDON and NAPLES.

Engliſh money is reduced to that of Naples by ſaying; as the rate of exchange is to 1 ducat, ſo is the given ſum to the ſum ſought.

Reduce 158*l.* 9*s.* 3*d.* to money of Naples; exchange at $37\frac{1}{2}$*d.* ſterling *per* ducat regno.

787 15 0 Engliſh.

Arbitration of Exchange.

Arbitration of exchange is a compariſon between the courſes of exchange of ſeveral places in order to aſcertain the moſt advantageous method of drawing or remitting bills. It is diſtinguiſhed into ſimple and compound arbitration; the former comprehends the exchanges of three places only, and the latter of more than three places.

Simple Arbitration

Is a compariſon between the exchanges of two places with reſpect to a third; that is to ſay, it is a method of finding ſuch a rate of exchange between two places, as ſhall be in proportion with the rates quoted between each of them and a third place. The exchange thus determined, is called the *arbitrated price*, and alſo *proportional exchange*; and the *proportional par*.

If, for example, the courſe between London and Paris be 24 francs for 1*l.* ſterling, and between Paris and Amſterdam 54*d.* Flemiſh for 3 francs, (that is, 36*s.* Flemiſh for 24 francs,) the arbitrated price between London and Amſterdam, through Paris, is evidently 36*s.* Flemiſh for 1*l.* ſterling: for as 3 fr. : 54*d.* Flem. :: 24 fr. : 36*s.* Flem.

Now when the actual direct price (as ſeen by a quotation or otherwiſe adviſed,) is found to differ from the arbitrated price, advantage may be made by drawing or remitting indirectly, that is, by drawing on one place through another, as on Amſterdam through Paris; which may be performed in three different ways.

1ſt. London may draw on Paris, and order his correſpondent there to draw on Amſterdam.

2d. London may draw on Paris, and order his correſpondent in Amſterdam to remit the ſame ſum to Paris.

3d. London may order his correſpondent at Paris to draw on Amſterdam, and to remit the value to London.

The operation of remitting indirectly, or of remitting to one place through another, may be likewiſe performed in three different ways:

1ſt. London may remit to Paris, and order his correſpondent there to remit the ſum to Amſterdam.

2d. London may remit to Paris, and order his correſpondent in Amſterdam to draw on Paris.

3d. London may take bills on Paris, and remit them to Amſterdam, there to be negociated.

To exemplify this by familiar illuſtrations, ſuppoſe the arbitrated price between London and Amſterdam to be as before ſtated, 36*s.* Flemiſh for 1*l.* ſterling; and ſuppoſe the direct courſe, as given in Lloyd's liſt, to be 37*s.* Flemiſh, then London, by drawing directly on Amſterdam, muſt give 37*s.* Flemiſh for 1*l.* ſterling; whereas, by drawing through Paris, he will give only 36*s.* Flemiſh for 1*l.* ſterling: it is therefore the intereſt of London to draw indirectly on Amſterdam through Paris.

On the contrary, if London remits directly to Amſterdam, he will receive 37*s.* Flemiſh for 1*l.* ſterling; whereas, by remitting through Paris, he will receive only 36*s.* Flemiſh: it is the intereſt of London therefore to remit directly to Amſterdam.

Example 2.—Suppoſe the exchange of London on Liſbon to be at 68*d.* *per* milree, and that of Liſbon on Madrid 500 rees *per* dollar, the arbitrated price between London and Madrid is 34*d.* ſt. *per* dollar; for as 1000 rees : 68*d.* :: 500 rees : 34*d.* But if the direct exchange of London on Madrid be 35*d.* ſterling *per* dollar, then London, by remitting directly to Madrid, muſt pay 35*d.* for every dollar; whereas by remitting through Liſbon he will pay only 34*d.*: it is therefore the intereſt of London to remit indirectly to Madrid through Liſbon.

On the contrary, if London draws directly on Madrid, he will receive 35*d.* ſterling *per* dollar; whereas, by drawing indirectly through Liſbon, he would receive only 34*d.*: it is therefore the intereſt of London to draw directly on Madrid.

From theſe examples, the two following rules are manifeſt.

Rule 1.—Where London gives the certain price, draw through that place which gives the loweſt arbitrated price, and remit through that which produces the higheſt.

Rule 2.—Where London gives the uncertain price, draw through that place which produces the higheſt arbitrated price, and remit through that which gives the loweſt.

What is ſaid here of London will equally apply to any other place from whence the operation is made.

Suppoſe the exchange of London on Amſterdam to be 34.6; on Genoa, 47; on Leghorn, 52; and the exchange of Amſterdam on Genoa, 86; on Leghorn, 93; what is the moſt advantageous method for London to remit to, or draw on Amſterdam?

1ſt.—Becauſe 47*d.* ſt. give 1 pezza in Genoa, and this pezza in Amſterdam gives 86*d.* Flemiſh, ſay, as 47*d.* ſt. : 86*d.* Flemiſh :: 240*d.* ſt. : 439*d.* Flemiſh, or 36*s.* 7*d.* Flemiſh, which is the arbitrated price through Genoa.

2d.—Becauſe 52*d.* ſt. give 1 pezza in Leghorn, and this pezza in Amſterdam gives 93*d.* Flemiſh, ſay, as 52*d.* ſt. : 93*d.* Flemiſh :: 240*d.* ſt. : 429*d.* Flemiſh, or 35*s.* 9*d.* Flemiſh, which is the arbitrated price through Leghorn.

Hence, according to the firſt rule, the intereſt of London is *to draw* directly on Amſterdam, inſtead of drawing through Genoa or Leghorn; and *to remit* through Genoa, inſtead of remitting directly to Amſterdam, or indirectly through Leghorn.

And according to the ſecond rule, the intereſt of Amſterdam would be *to remit* directly to London, and *to draw* on London through Genoa.

Compound

Compound Arbitration

Is a compariſon between the exchanges of more than three places in order to find how much a remittance paſſing through them all will amount to at the laſt place, or to find the arbitrated price between the firſt place and the laſt, and thus to determine on the moſt advantageous mode of negociating bills.

Compound arbitration is therefore a repetition of ſimple arbitration, and may be ſolved by a continuation of ſeveral ſtatings in the Rule of Three; but all ſuch operations are beſt performed by conjoint proportion; commonly called the "Chain rule," which ſhall be here explained and demonſtrated, after giving an example of compound arbitration by the Rule of Three.

Suppoſe the exchange between London and Amſterdam to be 35 ſhillings Flemiſh for 1 *l.* ſterling; between Amſterdam and Liſbon, 42 pence Flemiſh for 1 old cruſade; and between Liſbon and Paris, 480 rees for three francs, what is the arbitrated exchange between London and Paris?

1ſt. As 35*s.* Flem. : 1*l.* :: 42*d.* Flem., or 3½*s.* Flem. : 2*s.* ſt. = 1 old cruſade.

2dly. As 1 old cruſade, or 400 rees : 2*s.* ſt. :: 480 rees : 2*s.* 4⅘*d.* ſt. = 3 francs.

3dly. As 2*s.* 4⅘*d.* ſt. : 3 francs :: 240*d.* ſt. : 25 francs.

Hence the arbitrated price is 25 francs for 1 *l.* ſterling.

The Chain Rule explained and demonſtrated.

Diſtinguiſh the ſeveral courſes of exchange into antecedents and conſequents, and place them in two columns, the antecedents to the left and the conſequents to the right, by way of equation.

The firſt antecedent muſt be of the ſame denomination as the quantity of which the value is required.

The firſt conſequent muſt be of the ſame denomination as the ſecond antecedent, and the ſecond conſequent as the third antecedent; and ſo on throughout.

The laſt conſequent muſt be of that denomination in which the anſwer is required.

The terms being thus arranged, the antecedents muſt be multiplied continually for a diviſor, and the conſequents for a dividend; and the quotient will be the anſwer.

The calculation may be abridged by expunging ſuch antecedents and conſequents as are alike, and reducing ſuch their loweſt terms as admit of a common diviſor.

Example from the foregoing Queſtion.

1 *l.* Sterling = 35 Shillings Flemiſh.
3½ Shillings Flemiſh = 400 Rees
480 Rees = 3 Francs.

How many francs will 1 *l.* ſterling give?

$$\frac{3 \times 400 \times 35}{1 \times 480 \times 3\frac{1}{2}} = \frac{42000}{1680} = 25 \text{ francs.}$$

In this example, 480 and 400 have the common diviſors 8 and 10, and they may therefore be reduced to 5 and 6; again the antecedent 6 may be reduced to 2, by ſtriking out the firſt conſequent 3; the fraction is therefore reduced to $\frac{5 \times 35}{2 \times 3\frac{1}{2}} = \frac{175}{7} = 25$, as before.

Demonſtration of the Chain Rule.

Let A, B, C, D, &c. be ſeveral denominations of money, and *m. n, p, q,* &c. the numbers or quantities of thoſe denominations, and let them ſtand thus:

Antecedents. . . . *Conſequents.*
m A . . = . . n B
p B . . = . . q C
r C . . = . . s D
t D . . = . . v E

Now to find what number of the laſt denomination (E) is equal to a given number of the firſt denomination (A) let z times the laſt term = y times the firſt, that is, let $z\,\text{E} = y\,\text{A}$.

Multiply all theſe equations together, the antecedents by the antecedents, and the conſequents by the conſequents, which will give $m\,\text{A} \times p\,\text{B} \times r\,\text{C} \times t\,\text{D} \times z\,\text{E} = n\,\text{B} \times q\,\text{C} \times s\,\text{D} \times v\,\text{E} \times y\,\text{A}$, and this equation reduced is $mprtz = nqsvy$.

Now if the number of the laſt denomination be required, $z = \frac{nqsvy}{mprt}$; but if the number of the firſt denomination be required, $y = \frac{mprtz}{nqsv}$. *Q. E. D.*

Example 2.—If London remit 1000 *l.* ſterling to Cadiz by way of Holland at 35 *s.* Flemiſh *per* pound ſterling; thence to France at 58 *d.* Flemiſh *per* ecu of 3 francs; and thence to Cadiz at 15½ francs *per* doubloon of 4 dollars, what is the price between London and Cadiz reſulting from the operation? and how many dollars will the 1000*l.* amount to in Spain?

1 Pound ſterling = 35 Shillings Flemiſh
1 Shilling Flemiſh = 12 Pence Flemiſh
58 Pence Flemiſh = 3 Francs
15½ Francs = 1 Doubloon
1 Doubloon = 4 Dollars

How many dollars are equal to 1000 *l.* ſterling?

$$\frac{35 \times 12 \times 3 \times 4 \times 1000}{58 \times 15\frac{1}{2}} = \frac{5040000}{899} = 5606 \text{ dollars, 1 real,}$$

28 mar. which gives the exchange at 42¾ *d.* nearly.

The indirect courſe of exchange between London and Cadiz may be alſo found by an inverſe operation, called the *Doctrine of Contraries*: thus,

4 Dollars = 1 Doubloon
1 Doubloon = 15½ Francs
3 Francs = 58 Pence Flemiſh
12 Pence Flemiſh = 1 Shilling Flemiſh
35 Shillings Flemiſh = 240 Pence ſterling.

How many pence ſterling equal 1 dollar?

$$\frac{240 \times 58 \times 15\frac{1}{2}}{4 \times 3 \times 12 \times 35} = \frac{58 \times 15\frac{1}{2}}{3 \times 7} = \frac{899}{21} = 42\tfrac{17}{21}d.$$

Now if the direct courſe of exchange was above the indirect, the circular remittance would be moſt advantageous; but if under, the direct operation would be preferable.

In computing the profits or loſſes of exchange operations, allowance ſhould be made for the expences, commiſſion, and intereſt of money, all of which may be compriſed in the ſtatement by the Chain Rule; that is, by deducting them from thoſe terms of the conſequents to which they may relate; thus, in the following example, the *per centage* is ſubtracted from 100 in the laſt place of the conſequents.

Example 3.—London takes bills on Madrid at 33½*d. per* dollar of exchange, remits them to Amſterdam, with orders to negociate at 90¼ grotes *per* ducat of exchange, and make the returns in bills on Paris at 51⅜ grotes *per* ecu of 3 francs: what does London gain or loſe *per cent.* by this operation, ſuppoſing the bills on Paris are negociated at 25 livres 18 ſous *per* pound ſterling; and that all the charges, including intereſt for the time that London is out of its money, amount to 1⅛ *per cent.*?

33½ Pence ſterling = 272 Maravedis
125 375 Maravedis = 90¼ Grotes
51⅜

51⅛ Grotes = $\cancel{2}$ Francs
4 $\cancel{80}$ Francs = 81 Livres
1 Livre = $\cancel{20}$ Sous
259 $\cancel{518}$ Sous = $\cancel{240}$ Pence ſterling 120
$\cancel{100}$ Pence ſterling = 98⅞ On account of charges.

How much does $\cancel{100}$ *l.* ſterling give?

$$\frac{272\times 90\frac{1}{2}\times 81\times 98\frac{7}{8}}{33\frac{1}{2}\times 125\times 51\frac{1}{8}\times 4\times 259\times 100} = 105{,}853, \text{ anſwer.}$$

The profit is therefore 5*l.* 17*s.* 0¾*d.* *per* 100*l.* ſterling.

Operations in compound arbitration may be greatly facilitated by the help of logarithms: thus, "from the ſum of the logarithms of the conſequents, ſubtract the ſum of the logarithms of the antecedents; the difference will be the logarithm of the anſwer."

In this caſe, however, the reduction of the numbers as above is ſuperfluous, as it is as eaſy to find the logarithm of a large as of a ſmall number; but when equal terms are on both ſides they ſhould be ſtruck out; and if a common diviſor can be found which will reduce any term to unity, it will likewiſe ſhorten the operation.

In queſtions of this kind much time and labour may be ſometimes ſaved by making uſe of *fixed numbers*; thus, where ſeveral terms are unchangeable in both the antecedents and conſequents they can be reduced to one; and the conſtant logarithm of this number may be uſed with thoſe that vary; ſuch as the logarithms of the rate of exchange, the amount of the charges, &c.

Beſides the foregoing rules for facilitating the arbitration of exchange, various other methods have been propoſed for ſhortening and illuſtrating the ſubject; even triangles and other diagrams have been conſtructed for this purpoſe; (ſee Poſtlethwait's Commercial Dictionary, vol. i. p. 94.) but geometrical projections do not ſeem well adapted to elucidate this rule.

A graphic operation, however, of a very uſeful and ingenious deſcription, has been lately executed in London, in which ſcales of the monies of exchange of the principal places in Lloyd's liſt are ſo graduated and arranged, that the arbitrated price between any two of them, with reſpect to a third place, may be immediately found by the application of a right line. The invention is by William Wollaſton, M.D. S. and F.R.S.

We ſhall conclude this article by giving rules for calculating the intrinſic par of exchange, and alſo tables of the ſame in gold and ſilver according both to mint regulations, and to aſſays.

The intrinſic par of exchange may be calculated by the rules laid down for computing the value of coins. (See Coin.) But the operation may be performed with greater preciſion by the Chain rule, as in the following examples.

Example 1.—What is the intrinſic par between London and Liſbon, in *gold*, when taken from the Johaneſe of 6400 rees, which, according to the mint regulations of Portugal, contains 221⅖ grains of Engliſh ſtandard gold?

6400 Rees = 221⅖ Grains of ſtandard gold
480 Grains ſtandard gold = 934½ Pence ſterling.

How many pence ſterling will 1000 rees give?

Striking out the common diviſor 1000, $\frac{221\frac{2}{5}\times 934\frac{1}{2}}{64\times 48} =$ 67,35*d.* ſterling for the milree.

Example 2.—What is the intrinſic par between London and Madrid, in *ſilver*, the weight of the dollar being 17 dwt. 8 gr. Troy, and its fineneſs 8 dwt. worſe than Engliſh ſtandard, according to average aſſays lately made at his majeſty's mint at the Tower of London.

85 Dollars of exchange = 64 Hard dollars
1 Hard Dollar = 416 Grains Troy
222 Grains in dollars = 214 Grains ſtandard
480 Grains ſtandard = 62 Pence ſterling.

How many pence ſterling does 1 dollar of exchange give?

Striking out the common diviſor 64, $\frac{416\times 214\times 62}{85\times 111\times 15} =$ 39*d.* ſterling for the dollar of exchange.

Example 3.—What is the intrinſic par between London and Amſterdam, in *ſilver*, when taken from the rixdollar current, which weighs 18 dwt. Troy, and is (according to aſſays) 16 dwt. worſe than Engliſh ſtandard, taking the agio of banco on currency at 4 *per cent.*

62 Pence ſterling = 20 Dwt. ſtandard ſilver
202 Dwt. ſtandard = 222 Dwt. in rixdollars
18 Dwt. or 1 rixdollar = 50 Stivers currency
1 Stiver = 2 Grotes
12 Grotes = 1 Shilling Flemiſh
104 Shillings Flemiſh currency = 100 Shillings Flemiſh banco.

How many ſhillings Flemiſh banco do 240 pence ſterling give?

Brought down and reduced.

31	$\cancel{62}$	$\cancel{20}$	5
103	$\cancel{208}$	$\cancel{222}$	37
5	$\cancel{18}$	50	50
	$\cancel{12}$	$\cancel{2}$	.
13	$\cancel{104}$	$\cancel{100}$	25
		$\cancel{240}$	20

$\frac{5\times 37\times 50\times 25\times 20}{31\times 103\times 3\times 13} =$ 37*s.* 2*d.* Flemiſh for the pound ſterling.

Table of the intrinſic par of exchange between London and the principal places in Lloyd's liſt, gold againſt gold, and ſilver againſt ſilver, calculated according to the mint regulations of each place reſpectively.

From the two foregoing tables it appears, that the par in gold generally varies from that in ſilver, and in ſome places very conſiderably.

It alſo appears that the aſſays do not differ eſſentially from the mint regulations; but where any difference is found to exiſt, it is moſtly in deficiency.

The intrinſic par of exchange between any other places, beſides the above, may be determined by the foregoing rules, and from the money tables in the preſent article, with thoſe given in the article Coin.

It ſhould be obſerved, that in the calculation of the par for Amſterdam, the ducat is reckoned at 5 florins 5 ſtivers currency, but this price is ſubject to alteration, and therefore no permanent par in gold can be eſtabliſhed with Holland, even if the agio were fixed. It ſhould be alſo remarked, that in computing the par with Hamburgh the ducat is reckoned at 6 marks Hamburgh banco, and the Cologne mark of fine ſilver at $27\frac{5}{8}$ marks banco, which are the common, but not conſtant prices, and therefore no permanent par can be eſtabliſhed with Hamburgh, any more than with Amſterdam.

Authors on exchange are very numerous, though few can be mentioned that have produced full and accurate ſyſtems: the principal are, Kruſe of Hamburgh; Ricard of Amſterdam; Gerhardt of Berlin; Marien of Spain; Senebier of Geneva; Giraudeau, Ruelle, Reiſhammer, and Corbaux of France; and Duboſt of London. Among the productions of thoſe writers Kruſe's Hamburgh Contoriſt has been the moſt univerſally approved; an Engliſh tranſlation of this ſyſtem of exchanges, monies, weights and meaſures, with conſiderable additions and alterations, is now nearly printed, and will be ſhortly publiſhed, under the title of the "Univerſal Cambiſt;" from which the preſent article has been chiefly extracted.

Exchange alſo denotes a public place, in moſt conſiderable cities, wherein the merchants, negociants, agents, bankers, brokers, interpreters, and other perſons concerned in commerce, meet, on certain days, and certain times thereof, to confer, and treat together of matters relating to exchanges, remittances, payments, adventures, aſſurances, freightments, and other mercantile negociations both by land and ſea.

In Flanders, Holland, and ſeveral cities of France, theſe places are called *bourſes;* at Paris and Lyons, *places de change;* and in the Hanſe towns, *colleges of merchants.*

Theſe aſſemblies are held with ſo much exactneſs, and merchants and negociants are ſo indiſpenſably required to attend at them, that a perſon's abſence alone makes him be ſuſpected of a failure or bankruptcy.

The moſt conſiderable exchanges in Europe are that of Amſterdam, and that of London, called the Royal Exchange. For an account of the latter, ſee Royal *Exchange.*

The former is a large building, 230 feet long and 130 broad, round which runs a periſtyle or portico, 20 feet wide. The columns of the periſtyle, amounting to 46, are numbered, for the convenience of finding perſons.

That of Antwerp was little inferior to either of them, till a variety of circumſtances concurred to effect its ruin, and to transfer its trade to Amſterdam; the era of this important event in commercial hiſtory is about the year 1585.

Even in the time of the ancient Romans there were places for the merchants to meet, in moſt of the conſiderable cities of the empire. That ſaid by ſome to have been built at Rome in the year of the city 259, 493 years before our Saviour, under the conſulate of Appius Claudius and Publius Servilius, was called *collegium mercatorum;* whereof it is pretended there are ſtill ſome remains, called by the modern Romans *loggia*, the lodge; and now, uſually the "Place of St. George."

This notion of a Roman exchange is ſuppoſed to be founded on the authority of Livy, whoſe words are as follow; *viz.* "Certamen conſulibus inciderat, uter dedicaret Mercurii ædem. Senatus a ſe rem ad populum rejecit utri eorum dedicatio juſſu populi data eſſet, eum præeſſe annonæ, mercatorium collegium inſtituere juſſit." Liv. lib. ii. But it muſt be here remarked, that *collegium* never ſignified a building for a ſociety in the purer ages of the Latin tongue; ſo that "collegium mercatorum inſtituere" muſt not be rendered to build an exchange for the merchants, but to incorporate the merchants into a company. As Mercury was the god of traffic, this ædes Mercurii ſeems to have been chiefly deſigned for the devotions of this company or corporation.

Exchange, in *Law*, is a mutual grant of equal intereſts in lands or tenements, the one in conſideration of the other; and in our common law it more particularly denotes the compenſation which the warrantor muſt make the warrantee, value for value, if the land warranted be recovered from the warrantee. Bracton, lib. ii.

The word "exchange," is ſo individually requiſite and appropriated by law to the caſe now ſtated, that it cannot be ſupplied by any other word, or expreſſed by any circumlocution. (Co. Litt. 50, 51.) The eſtates exchanged muſt be equal in quantity (Litt. § 64, 65.), not of *value*, for that is immaterial, but of *intereſt;* as fee-ſimple for fee-ſimple, a leaſe for 20 years for a leaſe of 20 years, and the like. And the exchange may be of things that lie either in grant or in livery. (Co. Litt. 51.) But no livery of ſeiſin, even in exchanges of freehold, is neceſſary to perfect the conveyance

conveyance (Litt. § 62.); for each party ſtands in place of the other and occupies his right, and each of them hath already had corporal poſſeſſion of his own land. But entry muſt be made on both ſides; for, if either party die before entry, the exchange is void for want of ſufficient notoriety. (Co. Litt. 50.) And ſo alſo, if two parſons, by conſent of patron and ordinary, exchange their preferments; and the one is preſented, inſtituted, and inducted, and the other is preſented, and inſtituted, but dies before induction; the former ſhall not keep his new benefice, becauſe the exchange was not completed; and therefore he ſhall return back to his own. (Park, § 288.) For if, after an exchange of lands or other hereditaments, either party be evicted of thoſe, which were taken by him in exchange, through defect of the other's title, he ſhall return back to the poſſeſſion of his own, by virtue of the implied warranty contained in all exchanges. Blackſt. Comm. book ii. See Warranty.

Exchange *of goods and chattels*. See Sale.

Exchange, *the king's*, is the place appointed by the king for exchange of plate, or bullion for the king's coin. Theſe places have formerly been diverſe: but now there is only one, *viz.* that of the Tower of London, joined with the Mint.

Exchange, *bill of*. See Bill *of Exchange*.

What we call re-exchange, is the due, or premium of a ſecond exchange, when a bill is proteſted. See Re-exchange.

Exchange *brokers*. See *Exchange* Brokers.

Exchange *of Priſoners*. This meaſure, which is dictated both by humanity, and, in general, by mutual intereſt, is frequently adopted by two hoſtile nations, for the purpoſe of eaſing themſelves from the great charge incurred by the retention of priſoners of war in priſons, depots, &c. Sometimes an exchange becomes a conſideration while drawing up the articles of a capitulation; eſpecially where the beſiegers conſider it a matter of policy to get poſſeſſion of a fortreſs, without being too ſtrict in the conditions of ſurrender.

Thus we frequently obſerve, that a garriſon is allowed to retire, under the expreſs ſtipulation, that "no part thereof ſhall ſerve again until regularly exchanged." In ſuch caſe, an immediate liberation of an equal number of thoſe confined in the enemy's priſons ought inſtantly to take effect, and the perſons thus diſcharged ſhould be forwarded to their country; but if, as ſometimes occurs at the very commencement of a war, when one party has been extenſively ſucceſsful, the other may not have the means of equalization in regard to the liberation of priſoners, it may occur, that months, or even years, may elapſe, before ſuch reſtriction may be removed.

This, indeed, is not the only point on which the matter may reſt: it may ſometimes happen, that a prince may feel it to be his intereſt not to carry an exchange into effect; and this he may juſtify under the ordinary circumſtances attendant upon capitulation. Say, that an army ſurrenders ſimply under this condition; "that it ſhall not ſerve until duly exchanged." Here we ſee no obligation on the part of its ſuperiors to make any exchange: therefore, when policy dictates ſuch forbearance, we cannot affix any imputation on the prince, power, &c., if no exchange takes place.

If, indeed, the garriſon are allowed to return to their country, or to retire unmoleſted, on condition that "they *ſhall* be exchanged," then, we naturally expect, that no time will be loſt in liberating an equal number; adverting to the ſeveral claſſes of thoſe allowed to retire, and pairing them off in a correct manner.

We have heard of evaſions contrived for the expreſs purpoſe of detaining ſome individual, who, by his prowefs, or abilities, may have become highly obnoxious to the enemy. This, however, can only take place where there is no perſon of correſponding rank, againſt whom he can be paired off; then the exchange neceſſarily becomes in a degree arbitrary; though it is a matter of courteſy, to form ſome equivalent, in ſuch manner as may ſuit the wiſhes of his own government.

With a view to facilitate the exchanges occaſionally ordered, as well as to obviate the million of frivolous complaints which would elſe be made, it is cuſtomary for powers at war either to receive agents, or to appoint ſupervifors, whoſe duty is confined ſolely to ſuch matters as relate to the due ſubſiſtence of the priſoners, and to conducting whatever may relate to exchanges. Through this medium a government may always avail itſelf of the means of releaſing any particular perſons, confined as priſoners of war in the enemy's country; but, to effect this, at leaſt to be able to command it, there muſt be in its power ſome equivalent: for it would be unreaſonable to expect that a general officer ſhould be given up, when only a colonel could be offered in exchange; but a general may be liberated by any government, for the purpoſe of liberating any officer of inferior rank then in the power of the enemy: and ſo throughout.

EXCHANGERS are thoſe who return money beyond ſea, by bills of exchange, &c. called anciently alſo *excambiators*, and ſince *remitters*.

EXCHEQUER, or ſimply *Chequer*, originally denotes a cheſs-board; or a frame divided into ſixty-four ſquares, of two colours, whereon to play at draughts, cheſs, &c. See Chess, &c.

The word is formed from the French *eſchequier*, which ſignifies the ſame. Hence, trees are ſaid to be planted chequer-wiſe, *in quincuncem*, when diſpoſed ſo as to form diverſe ſquares repreſenting a chequer.

Exchequer is more particularly uſed for a chamber, or apartment, in Weſtminſter-hall, conſiſting of two parts; the court of exchequer and the lower exchequer. See Court *of Exchequer*, and Court *of Exchequer-chamber*.

Exchequer-*bills* are a ſpecies of paper firſt eſtabliſhed by Mr. Montague, in 1696, as a more convenient kind of ſecurity than the tallies and orders for repayment then in uſe, and alſo to ſupply the want of circulating caſh, during the re-coinage at that period. They were then taken at the exchequer for all payments of the revenue, and, when re-iſſued, they were allowed 7*l.* 12*s.* *per cent.* intereſt. They have ſince been iſſued yearly for anticipating the produce of particular taxes; and they have almoſt conſtantly formed the principal article of that part of the public debt called the unfunded debt. Of late years the total amount of outſtanding exchequer bills (excluſive of thoſe charged on ſpecific branches of the revenue) has uſually been about 12 millions. The bank of England, ever ſince the year 1706, have been the contractors for their circulation, at a certain premium. The commiſſioners of the treaſury are empowered, by various ſtatutes, to borrow money, within a ſpecific ſum, limited by thoſe ſtatutes, by iſſuing exchequer bills on the credit of certain duties; which bills, by 12 Anne, cap. 11. and 12 Geo. I. cap. 11. bear an intereſt of 2*d.* a day *per cent.* payable to the bearers. But the intereſt payable on them has differed according to the current rate of intereſt at the time when they have been iſſued. Thoſe now in circulation bear intereſt at the rate of 3½*d.* a day *per cent.* They are often made for 100*l.* each, but of late years they have been chiefly for 1000*l.* each, and ſometimes for larger ſums. Theſe bills are numbered arithmetically, and regiſtered accordingly, ſo that the principal ſums may be paid off in courſe, the time of which is notified by public advertiſement. The ſaid exchequer bills ſhall be current to all receivers and collectors of the cuſtoms, exciſe, or any revenue, and at the receipt of the exchequer; and as any of them are paid or lent into the exchequer, the officers there ſhall cauſe tallies to be levied and delivered to the payers or lenders, as if they had made ſuch payments or loans in ſpecie. The inſtalments on loans are paid into the receipt of the exchequer in exchequer bills, which are received again by the bank as caſh, either for the amount of dividends due, or in repayment of advances. When theſe bills are ſold at a conſiderable diſcount, or any other circumſtance indicates that too many of them are in circulation, it is uſual to fund a part of them, that is, to convert them into a permanent debt by offering the holders of them ſtock in lieu of their bills. This of late has been frequently done. The total amount of exchequer bills iſſued for the public ſervice between the 5th of January 1808 and the 5th of January 1809, and not redeemed within that period, was 39,735,200*l.* The unfunded debt in exchequer bills, outſtanding on the 5th of January 1809, was 40,093,200*l.* The amount of exchequer bills iſſued for the public ſervice in Ireland, between the 5th of January 1808 and the 5th of January 1809, and not redeemed within that period, was 541,666*l.* 13*s.* 4*d.* If any exchequer bills be loſt, upon affidavit before a baron of the exchequer, and certificate from him, and ſecurity given to pay the ſame if found, duplicates are to be made out; and when bills are defaced new ones ſhall be delivered. Forging of theſe bills, or of the indorſements on them, is felony.

Exchequer, *meſſenger of the.* See Messenger.

Exchequer, *Black Book of the*, is a book under the keeping of the two chamberlains of the exchequer; ſaid to have been compoſed in 1175, by Gervaiſe of Tilbury, nephew of king Henry II. and divided into ſeveral chapters.

Herein is contained a deſcription of the court of England, as it then ſtood, its officers, their ranks, privileges, wages, perquiſites, powers, and juriſdiction; and the revenues of the crown, both in money, grain, and cattle. Here we find, that for one ſhilling, as much bread might be bought as would ſerve a hundred men a whole day; that the price for a fat bullock was only twelve ſhillings, and a ſheep four, &c. Larrey, p. i. p. 394. See alſo Domesday.

EXCISE, an inland duty, or impoſition, charged on commodities of general conſumption, and paid ſometimes upon the conſumption of the commodity, or frequently upon the retail ſale, which is the laſt ſtage before the conſumption. This mode of taxation was adopted among the Romans; for Auguſtus, after the civil wars, introduced an exciſe, which, though very moderate, was general. It ſeldom exceeded one *per cent.* but it comprehended whatever was ſold in the markets or by public auction, from the moſt conſiderable purchaſes of lands and houſes, to thoſe minute objects which can only derive a value from their infinite multitude and daily conſumption. Such a tax, however, as it affects the body of the people, has ever been the occaſion of clamour and diſcontent. Auguſtus was obliged to declare by a public edict, that the ſupport of the army depended in a great meaſure on the produce of the exciſe; and Tiberius diminiſhed the exciſe to one-half, though the relief was of very ſhort duration. It has been adopted, in more modern times, as the moſt economical mode of taxing the ſubject; the charges of laying, collecting, and managing the exciſe duties being conſiderably leſs in proportion than in other branches of the revenue. Beſides, it renders the commodity cheaper to the conſumer than charging it with cuſtoms to the ſame amount would do, becauſe this tax is generally paid in a much later ſtage of it. Nevertheleſs, the rigour and arbitrary proceedings of exciſe-laws ſeem hardly compatible with the temper of a free nation. For the frauds that might be committed in this branch of the revenue, unleſs a ſtrict watch is kept, makes it neceſſary, wherever it is eſtabliſhed, to give the officers a power of entering and ſearching the houſes of ſuch as deal in exciſeable commodities, at any hour of the day, and, in many caſes, of the night likewiſe. And the proceedings in caſe of tranſgreſſions are ſo ſummary and ſudden, that a man may be convicted in two days' time in the penalty of many thouſand pounds by two commiſſioners or juſtices of the peace; to the total excluſion of the trial by jury, and diſregard of the common law. Obnoxious as the exciſe duty has always been, it was firſt ſuggeſted by the earl of Bedford, lord treaſurer to king Charles I., but never actually introduced in that prince's reign. Its original eſtabliſhment took place in the year 1643, when it was introduced, on the model of the Dutch prototype, by the long parliament after its rupture with the crown; and its progreſs has been gradual. It was at firſt laid upon thoſe perſons and commodities, where it was ſuppoſed the hardſhip would be leaſt perceivable, *viz.* the makers and venders of beer, ale, cyder, and perry; and though it originated with the long parliament, the royaliſts at Oxford ſoon followed the example of their brethren at Weſtminſter, by impoſing a ſimilar duty; both parties, however, proteſting that it ſhould be continued no longer than to the end of the war, and then be utterly aboliſhed. But the parliament at Weſtminſter ſoon after impoſed it on fleſh, wine, tobacco, ſugar, and ſuch a multitude of other commodities, that it might be fairly denominated general. This was done in purſuance of the plan laid down by Mr. Pymme, who had been intended for chancellor of the exchequer under the earl of Bedford, and who ſeems to have been the father of the exciſe. In his letter to ſir John Hotham (30 May, 1643) he intimates, "that they had proceeded in the exciſe to many particulars, and intended to go on farther; but that it would be neceſſary to uſe the people to it by little and little." Having accuſtomed the people to it for ſome years, the ſucceeding champions of liberty boldly and openly declared (Ord. 14th Auguſt, 1649, ch. 50.) "the impoſt of exciſe to be the moſt eaſy, and indifferent levy that could be laid upon the people;" and accordingly it was continued during the whole uſurpation. Upon the reſtoration of king Charles II., as it had been long eſtabliſhed, and its produce was well known, ſome part of it was given to the crown, in 12 Car. II., by way of purchaſe for the feodal tenures and other oppreſſive parts of the hereditary revenue. (See Revenue.) Notwithſtanding its general unpopularity, it has been impoſed on abundance of other commodities in the reigns of king William III. and of every ſucceeding prince, towards ſupporting the enormous expences occaſioned by our wars on the continent. In the year 1732, the groſs produce of the exciſe-duty amounted to 2,964,617*l.* About this time ſir Robert Walpole, being of opinion, that taxes on conſumable commodities, to which every citizen contributes in proportion to his conſumption, and which, being included in the price of the commodity, are inſenſibly paid, conſtituted the moſt eligible mode of raiſing the revenue neceſſary for the public ſervice, formed a project for the gradual abolition, not only of the taxes on land, houſes, and windows, but alſo of the cuſtoms, by the ſubſtitution of productive exciſe duties. Fully apprized of the abuſes and frauds to which the collection of the cuſtoms was ſubject, and which he had no hope of remedying, he thought that the ſcheme of converting

ing the greater part of the cuſtoms into duties of exciſe, would be equally advantageous to government and to the fair trader; and that the exciſe laws might be ſo ameliorated, that, notwithſtanding the odium generally attached to them as arbitrary and oppreſſive, no juſt ground of complaint ſhould remain. With a view to the execution of this plan, he obtained a revival of the ſalt-duties, which had been repealed ſome years before; but upon propoſing, in the following year, to transfer the duties on wine and tobacco to the exciſe, "faction," ſays Dr. Smith (Wealth of Nations, vol. iii. p. 358.) "combined with the intereſt of ſmuggling merchants, raiſed ſo violent, though unjuſt a clamour againſt that bill, that the miniſter thought proper to drop it." The defeat of this ſcheme was celebrated by general rejoicings, as a deliverance from the greateſt political danger.

The ſeveral commodities now ſubject to exciſe duties are ale, beer, cyder, perry, mum, metheglin, and mead; things ſold by auction; bricks and tiles; candles; coaches and coachmakers; coffee, tea, chocolate, and cocoa-nuts; glaſs; hops; leather; linen cloths, ſilks, cottons, and callicoes; malt; paper; plate; ſalt; ſoap; ſpirituous liquors; ſtarch, hair-powder, and ſtone-blue; ſweets; tobacco and ſnuff; vinegar and verjuice; wine; and wire. See each of theſe articles.

In the year 1787 the various rates of duty which had been impoſed at different times were conſolidated; and other regulations were alſo adopted, by which the produce of the revenue was augmented, and the expence of collecting it materially reduced.

By 24 Geo. II. c. 40, all fines, penalties, and forfeitures, impoſed by this or any other act relating to the duties of exciſe, ſhall be ſued for, levied, recovered, or mitigated by ſuch ways and means as any fine, penalty, or forfeiture is or may be recovered or mitigated by any law or laws of exciſe, or in the courts at Weſtminſter, and ſhall be half to the king and half to him that ſhall inform or ſue:—that is to ſay, if within the limits of the chief office in London, the offence ſhall be determined by the commiſſioners (or any three of them, 1 Geo. II. ſt. 2. c. 16.) or, in caſe of appeals, by the commiſſioners of appeals; in all other places they ſhall be heard and determined by any two or more juſtices of the peace, reſiding near the place where the offence was committed, or forfeiture incurred; and in caſe of neglect or refuſal of ſuch juſtices, for the ſpace of fourteen days next after complaint made, and notice thereof given to the offender; then the ſub-commiſſioners may hear and determine the ſame; and if the party find himſelf aggrieved by the judgment given by the ſaid ſub-commiſſioners, he may appeal to the next quarter-ſeſſions, whoſe judgment therein ſhall be final. The ſaid commiſſioners for appeals, and chief commiſſioners for exciſe, and all juſtices of the peace and ſub-commiſſioners aforeſaid, are required, upon any complaint or information exhibited of any ſuch forfeiture made or offence committed, to ſummon the party accuſed, and upon his appearance or contempt to proceed to the examination of the fact, and on due proof thereof either by the voluntary confeſſion of the party, or by the oath of one credible witneſs, to give judgment or ſentence, and to iſſue warrants under their hands, for levying the ſame on the goods and chattels of the offender, and to cauſe ſale to be made thereof, if not redeemed in (not leſs than four, nor more than eight days, 27 Geo. II. c. 20.); and for want of ſufficient diſtreſs, to impriſon the party offending till ſatisfaction be made. The juſtices, commiſſioners, or ſub-commiſſioners, reſpectively, where they ſhall ſee cauſe, may mitigate, compound, or leſſen, the forfeiture, penalty, or fine; ſo as the ſame be not made leſs than double the value of the duty of exciſe which ought to have been paid, beſides the reaſonable coſts and charges of ſuch officers, or others as were employed therein, to be to them allowed by the ſaid juſtices. (12 C. II. c. 24.) No appeal in any cauſe of exciſe ſhall be admitted, till the appellant hath depoſited the ſingle duty with the commiſſioners or ſub-commiſſioners, and given ſecurity to the commiſſioners of appeal, or juſtices of the peace, where the cauſe is to be finally adjudged, for ſuch forfeiture as was adjudged againſt him. (15 C. II. c. 13.) By the ſame ſtatute all differences and appeals about the exciſe ſhall be heard in the proper county, and not elſewhere, and appeals within London and its limits, ſhall be within two months after judgment, and notice given or left at the dwelling houſe of the party, in all other places in four months and not otherwiſe.

By 43 Geo. III. c. 69, after fifth of July 1803, all duties, allowances, bounties and drawbacks of exciſe, and other duties under the management of the commiſſioners, granted by any act of parliament then in force, ſhall ceaſe; except in caſes relating to the recovery of arrears, or of any fine, &c. previouſly incurred. Provided that the act ſhall not extend to alter the duties upon malt, mum, cyder, and perry, granted by 43 Geo. III. c. 3. or upon malt, tobacco, and ſnuff, continued by 43 Geo. III. c. 4; (except as to the duties on tobacco licences, and on tobacco of Spain and Portugal): nor ſhall the act extend to the countervailing duties on importation from Ireland, or the drawbacks payable on exportation thither, according to the "Act of the Union;" (except thoſe in reſpect of beer, ale, and wines, bricks and tyles, cyder and perry, hops, mead or metheglin, ſpirits, vellum and parchment, gilt and ſilver wire, and gold and ſilver thread, lace or fringe.) And in lieu thereof ſhall be raiſed and collected upon the ſeveral goods, wares, merchandize, and commodities, deſcribed in ſchedules annexed to the ſaid act, and for the ſales by auction, and upon licences mentioned in one of theſe ſchedules, the ſeveral ſums and duties reſpectively ſet forth in the ſaid ſchedules; and that there be allowed in reſpect of goods, &c. for which any duty of exciſe is impoſed, the ſeveral drawbacks of exciſe as ſet forth in another ſchedule, and alſo all allowances directed to be made by any act in force on the ſaid 1ſt of July 1803, except as herein altered. And by 43 Geo. III. c. 81. certain additional duties inſerted in an annexed ſchedule are directed to be paid, and the drawbacks in another ſchedule ſhall be allowed; to commence from July 5, 1803, where no date is inſerted in the act, and the amount of the additional duties may be added to the price of articles contracted for prior to the act. And the ſaid new duties ſhall be raiſed, levied, collected, conſumed, paid, recovered, adjudged, mitigated, and allowed, (except where altered by theſe acts or either of them) in the like manner, and by ſuch means, ways, and methods as the former duties. And all conditions, regulations, rules, reſtrictions, and forfeitures; and every pain, penalty, fine, or forfeiture of any nature or kind whatſoever, for any offence againſt any act of parliament then in force; and the ſeveral clauſes, powers, and directions therein contained, (unleſs altered hereby,) ſhall extend to and be applied in the execution of theſe acts, in as full and ample manner as if the ſame were repeated and re-enacted in the body of theſe acts, 43 Geo. III. c. 69. § 4. c. 81. § 3. And in all caſes where duties are impoſed or drawbacks allowed by theſe acts on any ſpecific quantity of goods, the ſame ſhall apply after the ſame rate to any leſs quantity. Id.

The exciſe duties of England are under the management of nine commiſſioners, who ſit in the general "Exciſe office," having ſalaries of 1200*l.* a-year each, and they are obliged, by oath, to take no fee or reward, but from the king only. From theſe commiſſioners there lies an appeal to five others, called "Commiſſioners of Appeal." The commiſſioners of exciſe in Scotland are five in number, and have ſalaries of 600*l.* *per annum* each.

The number of officers employed in this branch of the revenue is very great. Beſide the commiſſioners above-mentioned, and their ſubordinate officers, as regiſters, meſſengers, &c. there is an auditor of the exciſe, and an auditor of hides, with their clerks, &c. A comptroller of caſh, and another of accompts, with their clerks; a regiſter; ſecretary; ſolicitor; receiver-general, with his clerks; clerk of ſecurities; ſtore-keeper; houſe-keeper; door-keepers; general accomptants, with their aſſiſtants; accomptant for fines, and two accomptants for the London brewery; clerk of the bills of exchange; examiners; clerk for ſuperviſors diaries; five general ſurveyors; general ſurveyors of diſtillery; and brandy; examiners of the diſtillery, of the brewery, and of ſoap and candles; ſurveyors of glaſs, of coaches, and plate licences; inſpector of ſpirituous liquors, licences, and coaches; inſpectors general of coffee, tea, &c. and of brewery through England and Wales. Beſide which, there are in England and Wales, excluſive of the bills of mortality, within which is the principal head office of exciſe, to which all other offices in the kingdom are ſubordinate and accountable, about fifty collectors, who go their reſpective rounds once in ſix weeks: the province of a collector comprehends ſeveral diſtricts, within each of which there is a ſuperviſor, under the inſpection of the collector; and each diſtrict is parcelled out into out-rides and foot-walks, within each of which there is an inferior officer, conſtituted under the hands and ſeals of the commiſſioners, or ſub-commiſſioners, in their reſpective diviſions, as neceſſity requires, and called gauger, or exciſeman, under the inſpection of the ſuperviſor, who every ſix weeks draws out a diary of every day's buſineſs, with remarks, and tranſmits it to the chief officer. Every perſon, previous to his appointment to the office of gauger, muſt procure a certificate of his age, which muſt be between 21 and 30; he muſt underſtand the four firſt rules of arithmetic, ſtate what buſineſs he hath followed, and that he is not encumbered with debts, be of the communion of the church of England, and, if married, not have more than two children; he muſt nominate two able perſons to be his ſureties; and the certificate, containing theſe particulars, and written by himſelf, muſt be ſigned by the ſuperviſor of the diſtrict where he lives, and accompanied with an affidavit, that he has uſed no bribes for obtaining this office. He is then ordered for inſtruction, under the care of an experienced officer, and to wait, under the denomination of an "expectant," till a vacancy happens. Upon admiſſion of officers of every kind relating to the exciſe, the oaths of allegiance and ſupremacy, and an oath of faithfulneſs in the execution of the particular office, muſt be taken, and the declaration againſt tranſubſtantiation muſt be ſubſcribed. The officers of exciſe are appointed, and may be diſmiſſed, replaced, or altered by the commiſſioners under their hands and ſeals; their ſalaries are allowed and eſtabliſhed by the treaſury: and by 1 William and Mary, c. 24. § 15. if it be proved by two witneſſes that any officer has demanded or taken any money, or other reward whatever, except of the king, ſuch offender ſhall forfeit his office. Officers of exciſe, taking a bribe, are liable to a forfeiture of 10*l.* 15 Car. II. cap. 11: and a perſon liable to exciſe duties offering them a bribe, &c. ſhall forfeit 500*l.* 11 Geo. cap. 30. Officers meddling in elections are ſubject to a penalty of 100*l.* and an incapacity of holding any office under the king, 5 W. cap. 20. And an officer, either of the exciſe or cuſtoms, dealing in exciſeable liquors, ſhall forfeit 50*l.* and be incapable of any office in the revenue, 12 Geo. cap. 28. The concealment of exciſeable goods is ſubject to a forfeiture of thoſe goods, and treble value, 11 Geo. cap. 30. Any perſon obſtructing an officer in the execution of his duty, ſhall forfeit 10*l.* 6 Geo. cap. 21. Actions of aſſault upon any officer may be tried in any county, 9 Geo. II. c. 35. And if any perſon ſhall diſturb or oppoſe any exciſe officer in the execution of the powers and authorities by this act granted, or any or either of them, except where other penalties are by the act provided, he ſhall forfeit 200*l.* 42 Geo. III. c. 38. And the ſame penalty is inflicted by 43 Geo. III. c. 81, in relation to that act. Officers of exciſe are empowered to ſearch at all times of the day, enter warehouſes, &c. And if officers ſuſpect that exciſeable goods are concealed in any place within the limits of the chief office of exciſe in London, upon oath by ſuch officers before the commiſſioners, or any two or more of them; or if ſuch place be in any other part of Great Britain, on oath before one or more juſtices of the county, &c. or ſuſpected place, ſetting forth the ground of ſuſpicion, the ſaid commiſſioners, or the ſaid juſtice or juſtices may, by ſpecial warrant, authoriſe ſuch officers by day or night (but if in the night, in preſence of a conſtable or other peace officer) to enter into ſuch place and to ſeize all ſuch goods; and if any perſon ſhall obſtruct any ſuch officers ſo authoriſed, or any one acting in the execution of ſuch warrant, he ſhall forfeit 100*l.* 42 Geo. III. c. 93. The officers, in their permits for removing exciſeable goods, ſhall expreſs as well the time for which they ſhall be in force for removing ſuch goods, as the time within which they ſhall be received into ſtock by the perſon to whom they are ſent; and if not removed within the time limited (unavoidable accidents excepted), or, in default of ſuch removing, if the permit ſhall not be returned to the officer who granted the ſame, the perſon procuring the permit ſhall forfeit treble value of the goods: and if not received into ſtock, within the time limited, by the perſon to whom they were permitted to be ſent, they ſhall be deemed goods removed without a permit. 21 Geo. III. c. 55. No writ ſhall be ſued out againſt any officer of exciſe, or his aſſiſtant, for any thing done in the execution of his office, until one calendar month's notice ſhall have been delivered to him, or left at his uſual place of abode, clearly and explicitly containing the cauſe of action, the name and place of abode of the perſon who is to bring ſuch action, and the name and place of abode of his attorney or agent: and the officer may at any time within ſuch month tender amends, and plead ſuch tender in bar of the action; and if, upon iſſue joined, the jury ſhall find the tender to have been ſufficient, they ſhall give a verdict for the defendant; but if the jury find that no amends, or ſuch as were not ſufficient, were tendered, they ſhall give a verdict for the plaintiff, and ſuch damages as they ſhall think proper with coſts of ſuit. 23 Geo. III. c. 70. If any action ſhall be brought againſt an officer, &c. it ſhall be brought within three months after the cauſe of action ſhall ariſe, and not afterwards, and ſhall be laid in the proper county; and if the plaintiff ſhall be nonſuited, or diſcontinue, or if upon a verdict or demurrer judgment ſhall be given againſt him, the defendant ſhall recover treble coſts.

The additional duties, which the progreſs of the public expenditure has rendered it neceſſary to impoſe, have greatly increaſed the produce of the exciſe, and rendered it the moſt important branch of the public revenue. The duties which it comprehends are divided into the permanent conſolidated duties, the temporary war taxes, and the annual duties; the latter conſiſt of the old annual malt duty, and of an additional malt duty, which, with ſome duties on tobacco and ſnuff, and ſome cuſtom duties, have, ſince the project for ſelling the land-tax, been granted annually in lieu thereof.

EXCISE.

An Account of the Groſs Actual Receipt in Money, Charges of Management, and Taxes repaid to Officers, Exp
Temporary War Taxes, and Malts and Tobacco, Annual in England, for the Year en
Exchequer, on each Article;—together with the Balance in the Hands of

	2,124,937	0	6

The total payments out of the revenue of exciſe, under the authority of warrants from the barons of exchequer, to the receiver-general of crown rents and caſualties in Scotland, from January 5, 1808, to January 5, 1809, are as follow:

	£.	s.	d.
Salaries to the judges and officers of the three courts of ſeſſion, juſticiary, and exchequer, and of the admiralty and commiſſary courts - - - - - - - -	50,340	12	10¾
Paid to thoſe on his majeſty's civil liſt eſtabliſhment, not belonging to the three courts - - - - - - - - - - -	22,727	10	10½
To Francis lord Napier, commiſſioner to the general aſſembly of the church of Scotland - - - - - - - - - - -	2,000	0	0
To John Connel, procurator for the church of Scotland, to be diſtributed by him among itinerant preachers - - -	1,000	0	0
To A. Mundell, without account	1,208	17	6
Total - -	77,277	1	3¼

The total revenue of inland exciſe and licences, together with other fees received by revenue exciſe collectors in Ireland, for one year, ending the 5th of January, 1809, amounted to 1,659,838*l.* 8*s.* 9¼*d.* and the total payments for management, militia, bounties, &c. out of the groſs and net revenue of exciſe, during the ſame period, amounted to 531,910*l.* 9*s.* 5*d.* If we add to the above ſum 1,659,838*l.* 8*s.* 9¼*d.* the amount of the inland duties, *viz.* 429,824*l.* 11*s.* 0⅜*d.* the groſs produce will amount to 2,089,662*l.* 19*s.* 9⅝*d.* and the amount of the net produce was 1,772,615*l.* 16*s.* 2⅞*d.*

EXCISION, in *Surgery*, is a word often uſed to ſignify the operation of cutting any tumour, or any foreign ſubſtance, off, or out of, a part of the body.

EXCITABILITY, in Dr. John Brown's hypotheſis, or the *Brunonian* hypotheſis, as it has been called, is nearly ſynonymous with the *vital principle* of medical writers in general, and ſignifies that quality or property of living beings, on which the phenomena of life depend.

Life itſelf is, in the opinion of Brown, a *forced ſtate*, ariſing altogether from the action of certain agents, which he denominates *exciting* powers, upon the *excitability*; for death enſues equally, whether the exciting powers are withdrawn, or the excitability is loſt. The exciting powers conſiſt of heat, air, food, drink, and other ſubſtances taken into the ſtomach, the blood, and the fluids ſecreted from it; as well as of certain functions of the ſyſtem itſelf, ſuch as muſcular exertion, ſenſation, thought, and paſſion or emotion. The effect of the exciting powers acting upon the excitability, is denominated *excitement.*

This word "excitability" is to be conſidered as a general term, expreſſive of the facts aſcertained by obſervation, but of the eſſential nature of which we muſt remain ignorant; as in the caſe of gravitation, &c. "We know not what excitability is," ſays Dr. Brown, "or in what manner it is affected by the exciting powers. But whatever it be, whether a quality or a ſubſtance, a certain portion is aſſigned to every being upon the commencement of its living ſtate." He obſerves, however, that ſuch expreſſions as a determinate portion of excitability in each living being, the exhauſtion, or the accumulation of excitability, are neceſſarily borrowed from the qualities of material ſubſtances, in conſequence of the poverty of language; and are not to be received in a ſtrict and literal ſenſe.

Every power, then, that acts on the living frame, according to this doctrine, is ſtimulant, or produces excitement by expending excitability; whence "it follows, that the whole phenomena of life, every ſtate and degree of health and diſeaſe, are alſo owing to ſtimulus, and no other cauſe." By too great ſtimulation weakneſs is induced, becauſe the excitability becomes defective; this is ſaid to conſtitute a ſtate of *indirect debility;* when the exciting powers or ſtimulants are withheld or diminiſhed, weakneſs is likewiſe induced, the excitability being accumulated, or in exceſs; and this is denominated a ſtate of *direct debility.* (See DEBILITY.) For "this mutual relation obtains betwixt excitability and excitement; that the more weakly the powers have acted, or the leſs the ſtimulus has been, the more abundant the excitability becomes;—the more powerful the ſtimulus, the excitability becomes the more exhauſted." It is only then, when a mean degree of ſtimulus operates upon excitability at a medium, that perfect health is produced: in illuſtration of which a ſcale was drawn by Brown, (See Elements of Medicine, chap. iii. § 39. *note*) divided into 80 degrees of excitability oppoſed inverſely to 80 degrees of exciting power, at each end of which is *death*; there being, in the one caſe, 80 degrees of excitability, and no exciting power; and in the other, 80 degrees of ſtimulus and no excitability; whereas *perfect health* holds the middle ſtation, where there are 40 degrees of ſtimulus and of excitability reſpectively. Good health, however, may be conſidered to exiſt within a range of 30 or 40 degrees (15 or 20 on each ſide of the mean) in conſequence of the conſtant variation of ſtimulus, to which man is expoſed, in his food, drink, paſſions of the mind, &c.; but every departure from the mean of perfect health conſtitutes a pre-diſpoſition to diſeaſes of direct or indirect debility. As life is entirely regulated by excitement, and the exciting powers have a ſtimulating effect only, Dr. Brown affirms, that "the notion of health and diſeaſe being different ſtates is diſproved;" the operation of the powers producing or removing each ſtate being perfectly identical: and efficacious remedies being ſuch as oppoſe deficient ſtimulus to exceſſive excitement, and exceſſive ſtimulus to deficient excitement. In a word, there are but *two* forms of diſeaſes; and both are always preceded by pre-diſpoſition; thoſe which ariſe from exceſſive excitement are called *ſthenic* (from σθενος, *ſtrength,*) and thoſe which originate from a deficient excitement, *aſthenic.* The direct tendency of this hypotheſis, therefore, was to reduce the art of medicine to the ſimple regulation of ſtimuli, or of the exciting powers; it required us only to increaſe the quantity of ſtimulation on the one hand, or to withdraw, or rather diminiſh, the ſtimuli on the other, as the excitement happened to be too great or too little, above or below the medium of the ſcale of health.

As this conciſe ſtatement of a medical hypotheſis, which has excited great attention and much controverſy, may, perhaps, be obſcure to thoſe who are unaccuſtomed to the ſtudy of the phenomena of animal life, we ſhall cite an illuſtration of Brown's ſyſtem, drawn up by one of his pupils from a familiar operation, by which a conception of his fundamental principles may be facilitated.

"Suppoſe a fire to be made in a grate filled with a kind of fuel not very combuſtible, and which could only be kept burning by means of a machine, containing ſeveral tubes, placed before it, and conſtantly pouring ſtreams of air into it. Suppoſe alſo a pipe to be fixed in the back of the chimney, through which a conſtant ſupply of freſh fuel was gradually let down into the grate, to repair the waſte occaſioned by the flame, kept up by the air-machine.

The grate will repreſent the human frame; the *fuel* in it the *matter of life* (the *excitability* of Brown, and the *ſenſorial power* of Darwin): the tube behind, ſupplying freſh fuel, will denote the power of all living ſyſtems conſtantly to regenerate or reproduce excitability; while the air-machine, of ſeveral tubes, denotes the various *ſtimuli*, or exciting powers, applied to the excitability of the body; and the flame, drawn forth in conſequence of that application, repreſents *life*, the product of the exciting powers acting upon excitability.

As Dr. Brown has defined *life* to be "a forced ſtate," it is fitly repreſented by a flame, *forcibly* drawn forth, from fuel little diſpoſed to combuſtion, by the conſtant application of ſtreams of air poured into it from the different tubes of a machine. If ſome of theſe tubes are ſuppoſed to convey pure, or *oxygenous* air, they will denote the higheſt claſs of exciting powers, ſuch as opium, muſk, camphor, ſpirits, wine, &c. (the diffuſible ſtimuli of Dr. Brown) which bring forth for a time a greater quantity of life than uſual, as the blowing in of pure air into a fire will temporarily draw forth an uncommon quantity of flame. If others of the tubes be ſuppoſed to convey common or atmoſpheric air, they will repreſent the ordinary exciting powers, or ſtimuli, applied to the human frame, ſuch as heat, light, air, food, drink. &c.; while ſuch as convey impure airs may be uſed to denote what have formerly been termed ſedative powers, ſuch as poiſons, contagious miaſmata, foul air, &c. (Sedatives are deemed by Brown ſtimulants of a minor force.)

The reader will now be at no loſs to underſtand the ſeeming paradox of the Brunonian ſyſtem, that food, drink, and all the exciting powers applied to the body, though they *ſupport* life, yet they *conſume* it; for he will ſee, that the application of theſe powers, though it brings forth *life*, yet at the ſame time it waſtes the excitability, or *matter of life;* juſt as air blown into the fire brings forth more *flame*, but waſts the *fuel*, or *matter of fire*. This is conformable to the common ſaying, "the more a ſpark is blown, the brighter it burns, and the ſooner it is ſpent." A Roman poet has given us an excellent illuſtration of the Brunonian ſyſtem, when he ſays,

> "Balneæ, vina, Venus, conſumunt corpora noſtra;
> Sed vitam faciunt balnea, vina, Venus."
>
> "Wine, warmth, and love our vigour drain;
> Yet wine, warmth, love our life ſuſtain."

It will be equally eaſy to illuſtrate the two kinds of *debility*, termed *direct* and *indirect*, which, according to Brown, are the cauſes of all diſeaſes; if the quantity of ſtimulus, or exciting power, is proportioned to the quantity of excitability; that is, if no more excitement is drawn forth, than is equal to the quantity of excitability produced, the human frame will be in a ſtate of health; juſt as the fire will be in a vigorous ſtate, when no more air is blown in, than is ſufficient to conſume the freſh ſupply of fuel, conſtantly poured down by the tube behind. If a ſufficient quantity of ſtimulus is not applied, or air not blown in, the excitability in the man, and the fuel in the fire, will accumulate, producing *direct debility;* for the man will become *weak*, and the fire *low*. This, carried to a certain degree, will occaſion death to the firſt, and extinction to the laſt. If again, an over proportion of ſtimulus be applied, or too much air blown in, the excitability will ſoon be waſted, and the matter of fuel almoſt ſpent: hence will ariſe *indirect debility*, producing the ſame weakneſs in man, and lowneſs in the fire as before, and equally terminating, when carried to a certain degree, in death and extinction."

The ſimplicity of this doctrine, contraſted with the complicated hypotheſes of preceding phyſicians, and its happy illuſtration of ſome of the phenomena of life, (which we have noticed under the word Debility,) ſpeedily obtained for it a number of proſelytes, in the ſchools of medicine, wherever it was introduced. A generalization ſo ſweeping was, indeed, well calculated to arreſt the attention, and gratify the ardour of young minds; and accordingly it was eſpouſed with enthuſiaſm by the moſt ſanguine and ſpeculative ſtudents, and was debated and defended with a vehemence and intolerance of oppoſition, almoſt unknown in ſcientific diſcuſſions; and this not only at Edinburgh, where the doctrine originated, but ſucceſſively in the different univerſities of the continent to which it was carried. To learn that there were but two forms of diſeaſe, and therefore but two indications of cure, and two ſets of remedies, was particularly gratifying to thoſe who preferred indolent hypotheſis to the labour of obſervation. It ſuperſeded at once the practice and maxims of the Hippocratic ſchool of experience and unremitting inveſtigation, and reduced the art of medicine within the compaſs of a nut-ſhell.

But, true as this doctrine of excitement may be, in its application to many of the phenomena of life, it is by no means adequate to the explanation of the whole, and eſpecially of the cauſes and remedies of numerous diſeaſes: it is, moreover, inconſiſtent with itſelf in ſome points, and its advocates are not agreed in the interpretation of theſe difficulties.

There is one inconſiſtency ſo groſs and obvious, in the Brunonian doctrine, that it is inconceivable how the author could have been inſenſible of it, or have perſevered in maintaining it. In the illuſtration above quoted, a tube or chimney is provided, by which the fuel, or excitability, is ſuppoſed to be conſtantly repleniſhed: but no ſuch proviſion is mentioned by Brown. He affirms that "a certain portion of excitability is aſſigned to every being at the commencement of its exiſtence, that the action of ſtimuli neceſſarily exhauſts it, and that life conſiſts in the inceſſant action of ſtimuli upon this excitability;" *i. e.* in the inceſſant exhauſtion of it. With this ſtatement the notion of accumulated excitability (which is ſaid to conſtitute *direct* debility) is altogether incompatible: non-conſumption, or rather diminiſhed conſumption, might preſerve the excitability, but ſurely could never increaſe it: though ſomewhat might be ſaved, nothing could be gained, by the abſtraction of ſtimuli; and on the re-application of the diſcontinued ſtimuli, the excitability ſhould never be found increaſed or accumulated, but ſhould be ſtationary at the point of interruption; or, more correctly ſpeaking, it muſt always be found ſomewhat waſted, ſince, while life remains, it muſt be acted upon in ſome degree; while, on the other hand, every violent ſtimulation ſhould, upon the ſame principle, rapidly waſte, and haſten the irrecoverable exhauſtion of the powers of life. The propoſition, then, that a determinate portion of excitability is aſſigned to every individual, being equally inconſiſtent with the ſubſequent theorems of the ſyſtem, and with matter of fact, has been either given up, or explained away, by the pſeudo-Brunonians of the preſent day. They admit that the excitability may be partially reſtored or renewed by reſt and food. But to make the hypotheſis conſiſtent with common ſenſe, it requires that the proceſs of *generating* excitability be conſtantly going; for even during the moſt profound ſleep, ſtimuli, or, in other words, exhauſting powers, are inceſſantly applied, the ceſſation of all excitement being ſynonymous with death.

Another inconſiſtence in the hypotheſis, ſcarcely leſs palpable, is the ſtatement, that *indirect* debility, which conſiſts in exhauſtion of the excitability from exceſſive ſtimulation, is to be cured, *i. e.* the excitability is to be reſtored, by a continuance of ſtrong ſtimuli; namely, by ſtimuli "*little ſhort* of thoſe which produced the over-excitement." But, however managed, it is obvious from the hypotheſis, that they muſt exhauſt excitability, if they act at all; they muſt, therefore, wear out what remains of the excitability more and more, and ultimately exhauſt the power. No attempts to explain away this incongruity of language can be conſidered ſucceſsful; the alleged loſs of power in the ſtimuli, in conſequence of repetition, will only account for the leſs rapidity of the complete exhauſtion; but exhauſtion of excitability cannot be ſeparated from the notion of ſtimulation.

In its application to the practice of medicine, as well as to the explanation of the action of many cauſes of diſeaſe, the Brunonian ſyſtem is marked by a groſs neglect or defiance of obſervation and experience. The connections and dependencies of the different functions, the local derangements which take place in the different organs, and the curative indications deduced from theſe, are altogether overlooked; and the variety of phenomena which reſult from the ſpecific operation of various agents on the animal economy, is equally neglected. The aſſertion that all powers, which influence the animal body, whether productive or curative of diſeaſe, are *ſtimulant*, is an abuſe of language not often equalled by the framers of theories. There is not only not an identity in their action;—there is ſcarcely any thing in common. "With regard to contagions," to uſe the words of an intelligent critic, "when we conſider the regular and progreſſive ſeries of actions, induced by theſe on the ſyſtem; when we have obſerved that each contagion gives riſe to a train of peculiar and characteriſtic phenomena, defining the diſeaſe whence the contagion originated, and terminating often in the formation and ſeparation of a quantity of morbid matter, alone capable of propagating the ſame diſeaſe in others, we cannot acknowledge that identity in the operation of the exciting powers, which the Brunonians contend for. In diſeaſes induced by contagions, in the ſmall-pox, for example, or in lues venerea, we perceive ſomething more than ſimple excitement and unvaried ſtimulation. Individuals of every deſcription, whether prediſpoſed to ſthenia or aſthenia, whether labouring under direct or indirect debility, may be infected; and when the diſeaſe has taken place, it runs its courſe under every poſſible modification of the excitability, &c." (See Edinburgh Med. and Surg. Journal, vol. i. p. 369.) And again, with reſpect to the agents of the Materia Medica, beſides their action upon the excitability, or the degree of excitement and exhauſtion which they produce, there are various other peculiarities in their mode of operation. "They differ in the ſucceſſion of phenomena to which they give occaſion; the intoxication produced by wine, opium, and ſome other narcotics, cannot be imitated by aromatics, by the preparations of antimony or of mercury; nor the effects of theſe by narcotics: they differ in their power of ſpecifically affecting particular organs and functions, as the ſtomach, inteſtines, kidnies, ſkin, ſalivary glands, abſorbent or vaſcular ſyſtem, by emetics, purgatives, diuretics, ſudorifics, mercury, digitalis, &c. They differ in their power of oppoſing and inducing particular organic changes and morbid affections of the ſyſtem; as ſyphilis and biliary diſeaſes are cured by mercurials, ſcurvy by vegetable acids, and uric diſeaſes by alkalis: they differ in the durability of effect or change produced; as is obvious by comparing the momentary and fleeting effects of the diffuſible ſtimuli, with the permanent excitement and vigour produced by tonics, as by cinchona and preparations of iron, by wholeſome food and pure air." Loc. cit.

In ſhort, it is obvious that the word ſtimulant, as applied to all theſe various actions upon the living ſyſtem, no longer retains any definite meaning; but produces a jargon which may be interpreted by each individual according to his own notions. In this reſpect, the theory poſſeſſes an univerſal fitneſs, like Bayes' prologue, and will do for any practice that may be found moſt expedient. Thus mercury will be conſidered as the proper *ſtimulant* for ſyphilis, cinchona and arſenic for intermittents, citric acid for ſcurvy, and ſo on; for fortunately mankind have ſtill good ſenſe enough to accommodate their hypotheſes to the reſults of experience: hence we do not apprehend, that many of the moſt implicit believers in this jargon would endanger their patients by applying the ſame remedies to typhus, gout, and dropſy, becauſe they ſtand in the ſame numerical portion of the ſcale; or by treating phthiſis, apoplexy, and the plague alike, becauſe they are claſſed together in the ſame way!

Notwithſtanding its many inconſiſtencies and defects, however, the Brunonian doctrine has had ſome beneficial influence on medical ſcience, by inducing a particular attention to the degree of excitement, which accompanies many diſeaſes, although it cannot be conſidered as the cauſe or eſſence of them. The regulation of the excitement often conſtitutes the moſt uſeful means of conducting theſe diſeaſes through their courſe to a ſafe termination, by moderating ſymptoms, and keeping action within due bounds on the one hand, or ſupporting the languid forces of the ſyſtem on the other. This is eſpecially true with regard to contagious febrile diſeaſes.

The doctrines of Brown are contained in the "Elementa Medicinæ," which were firſt publiſhed in Latin, and afterwards tranſlated by himſelf. After his death a reviſed edition of this tranſlation was publiſhed by Dr. Beddoes, in 2 vols. 8vo. 1795; and another by the author's ſon, Dr. William Cullen Brown, in 3 vols. 8vo. in 1804. See BROWN.

EXCITATION, (from the Latin *excito*, I excite,) denotes the act of awakening, of rouſing, or of producing ſome power or action; thus we hear of the excitation of motion, excitation of heat, excitation of paſſions, &c. In natural philoſophy this word is principally uſed in the ſubjects of electricity and of heat; and of theſe two kinds of excitation the particulars are as follows.

When a piece of amber, or of glaſs, or of ſulphur, or in ſhort, of any other ſolid, called *electric*, or *non-conductor*, is obſerved in common, it does not appear to have any particular power; but if it be rubbed with a dry hand, or with ſomething elſe, then after a few ſtrokes it will be found that it has acquired the electric virtue, ſo that now it will attract ſmall bodies that are preſented to it, and it will alſo exhibit other electrical phenomena (for which ſee the article Electricity.) In this caſe the electric power in the amber, or glaſs, or ſulphur, is ſaid to have been *excited* by the friction of the hand or other body, which therefore is called the *rubber*; for, previous to the friction, the amber, or ſulphur, &c. ſhewed no ſigns of electricity, that power being, as it were, dormant in it.

Rubbing is the moſt general, and upon the whole, the moſt effectual method of exciting electrics, but there are ſeveral other modes of excitation, and indeed hardly any action, or any motion, takes place among natural bodies, which is not attended with the excitation of electricity. In general, however, the electricity is not produced in quantity ſufficient to affect our ſenſes, without the aid of proper inſtruments, and of courſe it paſſes unnoticed. The principal cauſes of the excitation of electricity are rubbing or friction, heating and cooling, melting or coagulating, evaporation and condenſation, expanſion and contraction, the mere juxtapoſition or contact of certain bodies, ſolution and efferveſcence, and laſtly ſome unknown action of the body in certain aquatic animals. But theſe methods are not indiſcriminately applicable to all ſubſtances. They are confined within certain limits of application as well as of effect; and of theſe particulars we ſhall now give a regular account.

Rubbing, or *friction*.—In the ſcience of electricity the various bodies of the earth are diſtinguiſhed into electric and conductors (ſee Electrics and Conductors;) and whenever two bodies are rubbed againſt each other, unleſs they be both very good conductors, ſome electricity is always produced; that is, one of the bodies acquires the poſitive or vitreous, and the other acquires the negative or reſinous electricity; for by this means one kind of electricity cannot be produced without the other. The circumſtance which, in the ſuperficial manner of performing the experiment, makes it appear as if one kind only of electricity were produced, is that the beſt conductor of the two bodies concerned, being not inſulated, loſes its electricity as ſoon as it receives it; but when both bodies are inſulated, each of them will become electrified by the friction, one of them acquiring the poſitive, and the other the negative electricity. Even two inſulated perfect conductors, by the leaſt contact or friction againſt each other, acquire a ſlight degree of electricity; but of this hereafter. The friction which is required for this excitation of electricity is not that which can ſcrape off or injure the ſurface, but a gentle preſſure progreſſively applied with a pretty quick motion. The former hard kind of friction generates heat, but little or no electricity.

The very ſame body, by changing the rubber, may be cauſed to acquire either the poſitive or the negative kind of electricity; and the change is often produced by a remarkably ſlight alteration of circumſtances, ſuch as altering the direction of the friction, increaſing or diminiſhing the temperature by a few degrees, and ſo forth. The following table exhibits the principal caſes of this kind of change, *viz.* it ſhews what kind of rubber is required for exciting a given body poſitively, and what kind for exciting it negatively. Thus it appears that ſealing-wax acquires the poſitive electricity when rubbed with a metallic body, and that it acquires the negative electricity when rubbed with furs, leather, woollen cloth, &c. Thus alſo it ſhews that baked wood is excited poſitively by ſilk, and negatively by flannel.

Subſtance rubbed.	*Electricity.*	*Rubber.*
The fur on the back of a cat.	Poſitive	Every ſubſtance with which it has hitherto been rubbed.
Smooth glaſs.	Poſitive	Every ſubſtance hitherto tried, excepting
	Negative	The fur on the back of a cat.
Rough glaſs.	Poſitive	Dry oiled ſilk, ſulphur, metals.
	Negative	Woollen cloth, quills, wood, paper, ſealing-wax, white-wax, the human hand.
Tourmalin.	Poſitive	Amber, air, *viz.* by blowing with the bellows upon it.
	Negative	Diamond, the human hand.
Hare's ſkin.	Poſitive	Metals, ſilk, loadſtone, leather, hand, paper, baked wood.
	Negative	Other finer furs.
White ſilk.	Poſitive	Black ſilk, metals, black cloth.
	Negative	Paper, hand, hairs, weaſel's ſkin.
Black ſilk.	Poſitive	Sealing-wax.
	Negative	Hare's, weaſel's, and ferret's ſkin, the load ſtone, braſs, ſilver, iron, the human hand.
Sealing-wax.	Poſitive	Metals.
	Negative	Hare's, weaſel's, and ferret's ſkin, the hand, leather, woollen cloth, paper.
Baked wood.	Poſitive	Silk.
	Negative	Flannel.

When two electric ſubſtances, equal in every reſpect, are rubbed againſt each other, that ſubſtance which ſuffers the greater degree of friction acquires the *negative*, and the other acquires the *poſitive* electricity. Thus, if a piece of ſilk, A, be drawn acroſs another piece of ſilk, B, in every reſpect equal to A, ſo that the ſurface of the whole piece, A, (*viz.* of one ſide of it,) be ſucceſſively drawn over one part of the piece B, then A will acquire the *poſitive*, and B the *negative* electricity. The reaſon of this probably is the greater degree of heat which the rubbed part of B acquires by the friction, it having been obſerved by Bergman, that heat rather diſpoſes bodies to acquire the negative electricity.

Glaſs, when warmed a little, as about the temperature of 110° of Fahrenheit's ſcale, may be excited more eaſily and more powerfully than at a lower temperature. A great part of this effect probably depends upon the glaſs being leſs apt to attract moiſture in that elevated temperature.

Mr. Henly inſulated ſeveral bodies, and in that ſtate rubbed them, one by one, againſt his woollen garments, or againſt ſilk, by which means they became electrified; but he obſerved very great irregularities in the effects which were produced by ſubſtances much allied to each other, or of the ſame claſs. Thus, a guinea, a ſix-pence, and a piece of tin, became negative; a piece of copper, a ſteel button, and a ſilver button, poſitive, at leaſt when the cloth was warm; animal ſubſtances, excepting ſhells, generally acquired the poſitive electricity; vegetables became almoſt always negative; but the ſmooth ſkins of bears became poſitive; common pebbles, marble, coal, and jet, acquired the negative electricity; gems and cryſtals, the poſitive; glazed wares and writing paper, the poſitive; tobacco pipe, elaſtic gum, a tallow candle, oiled ſilk, Indian ink, and blue vitriol, (*viz.* ſulphate of copper,) acquired the negative electricity. Other perſons have extended the liſt conſiderably farther, but it is uſeleſs to ſpecify the particulars.

The principal requiſite in the ſubject of electricity, is to determine the proper conſtruction of the rubber, and the method of employing it, ſo as to excite the greateſt poſſible power in a given electric.

The beſt rubber for a tube of ſmooth glaſs, Mr. Cavallo ſays, (Treatiſe on Electr.) is the rough ſide of black oiled ſilk, eſpecially when a little amalgam has been rubbed upon it; but the beſt rubber for a rough glaſs tube, a ſtick of baked wood, ſealing-wax, or ſulphur, is ſoft new flannel. The rubbers of common electrical machines, wherein a glaſs globe, or cylinder, or circular plate is revolved, has been varied and improved progreſſively. The more common conſtruction conſiſts of nothing more than a ſilk cuſhion ſtuffed with hair, over which is placed a piece of leather, and upon this leather ſome amalgam, (ſee AMALGAM *for electrical purpoſes*,) is ſpread ſo as to adhere pretty faſt to it. Some time ago it was cuſtomary, (and the practice even at preſent is not entirely laid aſide,) to make the rubber of red baſil ſkin ſtuffed with hair; but the above-mentioned ſilk one, which was contrived by Dr. Nooth, is much preferable. If this ſilk cuſhion, on account of adapting it to the ſurface of the glaſs, is to be fixed upon a metallic plate, then care ſhould be taken to render the plate free from ſharp points, edges or corners, and it ſhould be concealed or covered over with the ſilk. In ſhort, to conſtruct the rubber properly, it muſt be made ſo, that the ſide of it which the ſurface of the glaſs enters in whirling, may be as perfect a conductor as can be made, in order to furniſh an ample and ready ſupply of electricity, and the oppoſite part ſhould be as much a non-conductor as poſſible, in order that none of the electricity that has been accumulated upon the glaſs may go back to the rubber. A piece of ſilk is generally fixed to the extremity of the leather which ſtands againſt the ſurface of the glaſs. The rubber of Mr. Nairne's electrical machine (ſee ELECTRICAL *Machine*,) conſiſts of ſilk only put over the leather cuſhion, the piece of ſilk projecting a conſiderable way beyond the cuſhion, and very little amalgam is uſed with it: in truth no amalgam at all is put upon the rubber of this machine; but whilſt the clean rubber is on, and the cylinder is turning, a piece of leather, with ſome amalgam ſpread upon it, is applied for a few ſeconds to the under part of the cylinder, by which means a ſufficient number of particles of amalgam will fly along the ſurface of the glaſs, from the leather to the rubber.

The rubber ſhould be ſupported by a ſpring, by which means it may eaſily adapt itſelf to the inequalities of the ſurface of the glaſs, which, with cylinders, often are very conſiderable. It ſhould likewiſe be inſulated in whatever manner it may be moſt convenient; for whenever inſulation is not wanted, a chain or wire may be occaſionally hung upon it, by which means it will communicate with the ground or with any other body at pleaſure: when there is no poſſibility of inſulating the rubber, ſeveral of the moſt intereſting experiments in electricity cannot be performed with the machine.

Mr. Nicholſon made a great variety of experiments, reſpecting this mode of excitation, which are deſcribed at large in the Philoſophical Tranſactions for the year 1789, and from thoſe experiments he deduces the following inferences.

"Thoſe experiments," he ſays, "ſhew that the office of the ſilk is not merely to prevent the return of electricity from the cylinder to the cuſhion, but that it is the chief agent in the excitation, while the cuſhion ſerves only to ſupply the electricity, and perhaps increaſe the preſſure at the entering part. There likewiſe ſeems to be little reaſon to doubt but that the diſpoſition of the electricity to eſcape from the ſurface of the cylinder, is not prevented by the interpoſition of the ſilk, but by a compenſation after the manner of a charge, the ſilk being then as ſtrongly negative as the cylinder is poſitive; and, laſtly, that the line of light between the ſilk and the cuſhion in weak excitations, does not conſiſt of returning electricity, but of electricity which paſſes to the cylinder, in conſequence of its not having been ſufficiently ſupplied, during its contact with the rubbing ſurface.

"When the excitation was very ſtrong in a cylinder newly mounted, flaſhes of light were ſeen to fly acroſs its inſide, from the receiving ſurface to the ſurface in contact with the cuſhion, as indicated by the bruſh figure. Theſe made the cylinder ring as if ſtruck with a bundle of ſmall twigs: they ſeem to have ariſen from part of the electricity of the cylinder taking the form of a charge. This appearance was obſerved in a nine-inch, and a twelve-inch cylinder, and the property went off in a few weeks. Whence it appears to have been chiefly occaſioned by the rarity of the internal air produced by handling, and probably reſtored by gradual leaking of the cement."

In order to determine what takes place in the inſide of the cylinder, Mr. Nicholſon undertook a ſeries of experiments with a plate machine, (ſee ELECTRICAL *Machine*,) and from their reſult it appears, "that no advantage is gained by rubbing both ſurfaces, but that a well-managed friction on one ſurface will accumulate as much electricity as the preſent methods of excitation ſeem capable of collecting; but that when the excitation is weak, on account of the electric matter not paſſing with ſufficient facility to the rubbed ſurface, the friction enables the oppoſite ſurface to attract or receive it, and if it be ſupplied, both ſurfaces will paſs off in the poſitive ſtate, and either ſurface will give out more electricity than is really induced upon it, becauſe the electricity of the oppoſite ſurface forms a charge. It may be neceſſary to obſerve, that I am ſpeaking of the facts or effects produced by friction; but how the rubbing ſurfaces act upon each other to produce them, whether by attraction or otherwiſe, I do not here enquire."

From farther experiments with the cylinder, Mr. Nicholſon deduced the following concluſions: "the line, he ſays, of light on a cylinder departing from a ſimple cuſhion, conſiſts of returning electricity. 2. The projecting part of the cuſhion compenſates the electricity upon the cylinder, and by diminiſhing its intenſity prevents its ſtriking back in ſuch large quantities as it would otherwiſe do. 3. That if there were no ſuch compenſation, very little of the excited electricity would be carried off; and, 4. That the compenſation is diminiſhed, or the intenſity increaſed, in an higher ratio than that of the diſtance of the compenſating ſubſtance; becauſe if it were not, the electricity which has been carried off from an indefinitely ſmall diſtance, would never fly back from a greater diſtance, and from the edge of light.

“ I hope the conſiderable intenſity I ſhall ſpeak of will be an apology for deſcribing the manner in which I produce it. I wiſh the theory of this very obſcure proceſs were better known; but no conjecture of mine is worth mentioning. The method is as follows:

“ Clean the cylinder and wipe the ſilk.

“ Greaſe the cylinder by turning it againſt a greaſed leather till it is uniformly obſcured. I uſe the tallow of a candle.

“ Turn the cylinder till the ſilk flap has wiped off ſo much of the greaſe as to render it ſemi-tranſparent.

“ Put ſome amalgam on a piece of leather, and ſpread it well, ſo that it may be uniformly bright. Apply this againſt the turning cylinder. The friction will immediately increaſe, and the leather muſt not be removed until it ceaſes to become greater.

“ Remove the leather, and the action of the machine will be very ſtrong.

“ My rubber conſiſts of the ſilk flap paſted to a leather, and the cuſhion is preſſed againſt the ſilk by a ſlender ſpiral ſpring in the middle of its back. The cuſhion is looſely retained in a groove, and reſts againſt the ſpring only in ſuch a manner, that by a ſort of libration upon it as a fulcrum, it adapts itſelf to all the irregularities of the cylinder, and never fails to touch in its whole length. There is no adjuſtment to vary the preſſure, becauſe the preſſure cannot be too ſmall when the excitation is properly made. Indeed, the actual withdrawing of the cuſhion to the diſtance of one-tenth of an inch from the ſilk, will not materially affect a good excitation.

“ The amalgam is that of Dr. Higgins, compoſed of zinc and mercury. If a little mercury be added to melted zinc, it renders it eaſily pulverable, and more mercury may be added to the powder to make a very ſoft amalgam. It is apt to cryſtallize by repoſe, which ſeems in ſome meaſure to be prevented by triturating it with a ſmall proportion of greaſe: and it is always of advantage to triturate it before uſing.”

The following curious fact may, perhaps, be referred to the action of friction.—If a ſtick of ſealing-wax be broken into two pieces, the fractured parts, that is, thoſe extremities of the pieces which were contiguous to each other, will be found electrified, one of them poſitively, and the other negatively.

Heating and cooling.—The property of exhibiting electrical phenomena by means of heating and cooling, was firſt obſerved in a hard ſemi-pellucid foſſil, known under the name of tourmalin (called *aſchentrickker* by the Dutch, from its property of attracting aſhes, &c. when laid near the fire. Linnæus, in his Flora Zeylonica, calls it *lapis electricus.*) This ſtone, which generally is of a deep red or purple colour, and ſeldom exceeds the ſize of a ſmall walnut, is common in ſeveral parts of the Eaſt Indies, and eſpecially in the iſland of Ceylon. Tourmalins are alſo found in a great many other parts of the world, and often in pretty large maſſes, but they are moſtly opaque, and then they hardly ever ſhew any peculiar electric properties. (See its mineralogical characters under the article TOURMALIN.) The tourmalin's properties with reſpect to electricity are as follows.

1. The tourmalin, while kept in the ſame degree of heat, ſhews no ſigns of electricity; but it will become electrical by increaſing or diminiſhing its heat, and ſtronger in the latter than in the former circumſtance. An exceedingly ſmall variation of temperature is often ſufficient to render it ſenſibly electrical.

2. The electricity of the tourmalin does not appear all over its ſurface, but only on two oppoſite ſides, which may be called its *poles*, and they are always in one right line with the centre of the ſtone, and in the direction of its ſtrata; in which direction the ſtone is abſolutely opaque, though on the other ſemi-tranſparent.

3. Whilſt the tourmalin is heating, one of its ſides (diſtinguiſhed by A) is electrified plus, or poſitively, and the other ſide B, minus; but when it is cooling A is minus, and B is plus.

4. If it be heated and ſuffered to cool without either of its ſides being touched, then A will appear poſitive, and B negative, all the time of its heating or cooling.

5. If this ſtone be excited by friction, like any other electric, then each of its ſides, or both at once, may be made poſitive.

6. If the tourmalin be heated or cooled upon ſome other inſulated body, that body will be found electrified as well as the ſtone; and will be found poſſeſſed of the electricity contrary to that which is acquired by that ſide of the ſtone which was laid upon it.

7. The electricity of each ſide, or of both, may be reverſed by heating or cooling the tourmalin in contact with various ſubſtances; thus if it be cooled, or heated, in contact with the palm of the hand, that ſide of it, which would have been poſitive if cooled in the open air, is now negative; and that which would have been negative is now poſitive.

8. If a tourmalin be cut into ſeveral parts, each piece will have its poſitive and negative poles, correſponding to the poſitive and negative ſides of the ſtone from which it was cut.

9. Theſe properties of the tourmalin are alſo obſervable in vacuo, but not ſo ſtrongly as in the open air.

10. If this ſtone be covered all over with ſome electric ſubſtance, as ſealing-wax, oil, &c. it will in general ſhew the ſame appearances with this coating as without it.

11. Mr. W. Canton obſerved a very vivid light upon the tourmalin while heating in the dark; and this is ſufficient to point out which end of the ſtone is become poſitive, and which negative. Alſo, when the ſtone is ſtrongly excited, it emits very ſtrong flaſhes from the poſitive to the negative end, in the dark. That ſtone which is commonly called the “Braſilian emerald” from its colour, but which in fact is a tourmalin, alſo emits the abovementioned electrical light.

12. Laſtly, it is to be remarked that the power of the tourmalin is ſometimes injured by the action of a ſtrong fire, at other times it is improved, and frequently it is not at all affected by it. The laws, however, of ſuch uncertain effects, have not yet been inveſtigated.

Moſt of the above-mentioned properties, which were firſt obſerved in the tourmalin, have been found to belong to ſome other bodies; *i. e.* there are ſome other ſubſtances which have the electric virtue excited in them by heating and cooling. It is to be obſerved that ſuch bodies are generally, if not always, in a cryſtallized ſtate; alſo it has been remarked that the parts which exhibit the different ſtates of electricity differ from each other with reſpect to their form, although they are ſimilarly ſituated: while in thoſe cryſtals that are not electric, the ſimilarly ſituated parts correſpond alſo in form. If a cryſtal, for inſtance, conſiſt of a priſm terminated at each extremity by a pyramid,

mid, and theſe pyramids differ as to the kind of electricity they are capable of acquiring, it will be found that they alſo differ in their form ; one conſiſting of a greater number of ſurfaces than the other ; and the part which has the greater number of faces acquires the poſitive electricity ; the other the negative. Kidd's Outlines of Miner. vol. i.

The Abbé Haüy ſays, that the electricity which is produced by heat has been obſerved in ſix ſpecies of minerals, *viz.* the tourmalin, the borated magneſia or boracite, the topaz, whether from Brazil, from Saxony, or from Siberia, the meſotype of Haüy, or zeolite, the prehnite, and the oxydated zinc, or electrical calamine. See the nature of theſe minerals under the articles of their peculiar names. We are informed, however, that lately a gentleman, highly verſed in electrical experiments, examined a vaſt number of ſpecimens of the above-mentioned ſix minerals, and among them, (independent of the tourmalin,) he found two only that became electrical by heating and cooling ; namely, the boracite and the oxydated zinc ; with reſpect to a ſpecimen of the latter, which had a pyramid at one end, and was truncated at the other end, he particularly obſerved that whilſt cooling, the pyramid became negative, and the truncated ſide poſitive ; but whilſt heating, the pyramid became poſitive, though ſlightly ſo, and the truncated ſide did not manifeſt any ſenſible degree of electricity.

Melting or coagulating.—Melting or pouring a melted electric ſubſtance into another, excites electricity in various inſtances, and with peculiar phenomena.

If ſulphur be melted in an earthen veſſel, and be left to cool upon conductors ; then if taken out of the veſſel, when cold, it will be found ſtrongly electrical ; but not at all ſo, if it be left to cool upon electrics.

If ſulphur be melted in glaſs veſſels, and afterwards left to cool, they will both acquire a ſtrong electricity, the ſulphur negative, and the glaſs poſitive, whether they be left to cool upon electrics or upon conductors ; however, they always acquire a ſtronger power in the former caſe than in the latter ; and a ſtronger ſtill, if the glaſs veſſel is coated with metal. It is to be remarked, that the ſulphur acquires no electricity till it begins to cool ; its power increaſes in proportion as it contracts, and is the ſtrongeſt when in the ſtate of greateſt contraction ; but then the electricity of the glaſs veſſel is at the ſame time the weakeſt.

If melted ſulphur be poured into a veſſel of baked wood, it acquires the negative electricity, and the wood the poſitive ; but if it be poured into ſulphur, or rough glaſs, it does not acquire any ſenſible degree of electricity.

Melted ſulphur poured into a metal cup, and there left to cool, ſhews no ſigns of electricity whilſt remaining in the cup ; but if ſeparated, they will then appear ſtrongly electrified, the ſulphur poſitively, and the cup negatively. If the ſulphur is replaced in the cup, every ſign of electricity will vaniſh, but, if whilſt they are ſeparate the electricity of either of them is taken off, then, on being replaced, they will both appear poſſeſſed of that kind of electricity which had not been taken off.

Melted wax, poured into glaſs or wood, acquires the negative electricity, and leaves the glaſs or wood poſitive. But ſealing-wax poured into ſulphur acquires the poſitive electricity, and leaves the ſulphur negative. The wax-chandlers, in making their candles, often find it extremely difficult to prevent the attraction and adheſion of duſt and other light bodies, in conſequence of the electrified ſtate of the wax.

Chocolate freſh from the mill, as it cools in the pans in which it is received, becomes ſtrongly electrical. When turned out of the pans, it retains for ſome time this property, but ſoon loſes it by handling. Mr. Henly, who made theſe obſervations upon chocolate, found that by melting it again in an iron ladle, and pouring it into the tin pans as at firſt, would for once or twice more renew its power ; but when the maſs became very dry and powdery in the ladle, the electricity could no longer be revived by ſimple melting. However, he found that if in that ſtate a little olive oil be added and mixed well with the chocolate in the ladle, then on pouring it into the tin pan as at firſt, the electric power will be found to be completely recovered.

Evaporation and *condenſation.*—It was Mr. Volta who firſt diſcovered that the evaporation of water, and of moſt other bodies either ſolid or fluid that can be converted into ſmoke or vapour produced electricity, and not long after it was diſcovered that the condenſation of vapour alſo produced electricity, but of the contrary kind. Thus when water is evaporated from an inſulated veſſel, that veſſel remains electrified negatively, and if the vapour be received and condenſed upon an inſulated ſurface, that ſurface will acquire the poſitive electricity. Theſe diſcoveries, beſides their affording an eaſy explanation of the origin of the electricity in the clouds, fogs, &c. ſeem to point out a general law of nature ; namely, that the capacity of water or other fluids for holding the electric fluid, is increaſed by the expanſion of thoſe bodies into the form of vapour ; and is diminiſhed by the contrary operation, *viz.* by the contraction of the vapour into the form of water. Therefore, in the firſt caſe, by imbibing an additional quantity of electric fluid the vapour would leave the bodies from which it departed in a negative ſtate ; and in the ſecond caſe, *viz.* in the converſion of vapour into water by giving out a quantity of electric fluid, would leave the bodies that touched it in a poſitive ſtate. And this is analogous to what takes place with reſpect to caloric and vapour.

The eaſieſt way of ſhewing the production of negative electricity by evaporation is, to place a metallic cup upon a delicate electrometer, and to put a red-hot coal in it ; then on pouring a few drops of water upon the coal, a ſudden evaporation takes place, and the electrometer opens with negative electricity. In order to ſhew the poſitive electricity which is produced by the condenſation of vapour, let a pretty long wire (*viz.* about a foot long) proceed from the top of the electrometer, and fix ſome pieces of paper to the farther end of the wire, then if the ſteam of water which iſſues out of the ſpout of a boiling kettle be directed towards the paper, the ſteam will be condenſed upon it, and the electrometer will open with poſitive electricity.

The production of electricity by evaporation is not, however, always proportional to the quantity of evaporation ; for inſtance, when water is evaporated from certain ſubſtances it produces a conſiderable quantity of negative electricity, but when evaporated from certain other ſubſtances, it produces little of it or none at all. Thus the ſlaking of quicklime produces a copious evaporation, but no electricity ; and ſuch is likewiſe the caſe with a few other ſubſtances.

All the experiments that were made, during ſome years ſubſequent to the original diſcovery, ſhewed, that if evaporation produced any electricity at all, this was of the negative kind ; but at laſt two remarkable exceptions from this general rule were diſcovered, *viz.* one by a learned profeſſor of the academy of Mantua, and the other by Mr. Cavallo ; and theſe exceptions ſeem to point out a more intimate connection between the electric fluid and other bodies.

The firſt of the above-mentioned gentlemen found that when water is evaporated by being poured over a red-hot piece of very *ruſty* iron, it would leave the iron and veſſel upon which it ſtood electrified poſitively ; and the ſame would be the caſe if the red-hot piece of ruſty iron was thrown into the water : ſuppoſing that the latter is contained in an inſulated veſſel. If the iron be clean and free from ruſt, the electricity will be negative ; if very ruſty, the electricity will be poſitive, and if partially ruſty, it will acquire little or no electricity ; for in this laſt caſe the negative electricity which ariſes from the evaporation of water from over the clean part of the iron, is balanced by the poſitive electricity, which is produced by the evaporation from over the ruſty part. In conſequence of this, a ruſty piece of iron will not ſerve for more than one or two experiments, for, by rendering it red-hot, part of the ruſt is ſhaken off, and at laſt it will act like a piece of clean iron. Gardenii Diſſert. de Electrici Ignis Natura. § 84, 85, 86.

The other exception (which was diſcovered by Mr. Cavallo, and is publiſhed in the 4th edit. of his Treat. on El.) is ſhewn by means of red-hot glaſs. "The various degrees," Mr. C. ſays, "of electric powers that are produced by the evaporation of water from different ſubſtances induced me to diverſify the experiments as much as I could, in order to diſcover, if poſſible, the reaſon why thoſe different effects took place when the evaporation ſeemed to be equally quick and copious. Amongſt other ſubſtances I tried glaſs, and found that it generally produced little or no electricity. The water was ſometimes poured upon the hot glaſs, but in general the hot glaſs was dropped into the inſulated water which was contained in a tin cup. However, the difference of effect was found not to be occaſioned by thoſe two different modes of proceeding. Having repeated this experiment a great many times, I at laſt found that the effect depended upon the different nature of the glaſs. If white and clean flint glaſs be made red-hot, and in that ſtate be dropped into the veſſel of water, a quick evaporation will enſue, and the veſſel is electrified poſitively. If the flint glaſs be not very clear, there will not be any electricity generated by the evaporation. And, laſtly, if the experiment be tried with glaſs more impure, as that of which wine bottles are made, then the negative electricity will be produced.

"In performing this experiment, it is neceſſary to take care that no pieces of coal adhere to the glaſs, which will frequently happen when a piece of glaſs is heated in a common fire ; for in that caſe negative electricity will be produced by the evaporation, though the beſt flint glaſs be uſed."

Expanſion and *contraction*.—The mere expanſion of parts produces electricity in various inſtances ; ſuch as the diſperſion of powders by projection or blowing ; and the electrometer is affected by the ſame. It is owing to this electrified ſtate of the powders, that ſeveral curious phenomena are exhibited by them, which could not otherwiſe be explained. Thus the configurations which are produced by projecting powders upon an electrophorus, or upon any electrified ſurface, are owing, in great meaſure, to this cauſe ; thus alſo the duſt upon the roads when properly attended to is often found to expand itſelf more than it apparently ſhould, and to aſſume peculiar movements, in conſequence of its actual electrified ſtate, which may be eaſily diſcovered by means of a very delicate electrometer. For further particulars reſpecting this kind of excitation, ſee the article ELECTRICAL *Experiments*, and the deſcription of Mr. Bennet's gold-leaf electrometer, under the article ELECTROMETER. Mr. Cavallo, in his Treatiſe on Electricity, gives the following directions for exciting powders. "Inſulate," he ſays, "a metal plate upon an electric ſtand, and connect with it a cork-ball electrometer ; then the powder which is required to be tried, being held in a ſpoon, or other thing, at about ſix inches above the plate, is to be let fall gradually upon it. In this manner the electricity acquired by the powder, being communicated to the metal plate, and to the electrometer, is rendered manifeſt by the divergency of the threads ; and its quality may be aſcertained in the uſual manner."

"It muſt be obſerved, that if the powder is of a conducting nature, like the amalgam of metals, or ſand, &c. it muſt be held in ſome electric ſubſtance, as a glaſs phial, a plate of ſealing-wax, or the like. Sometimes the ſpoon that holds the powder may be inſulated ; in which caſe, after the experiment, the ſpoon will be found poſſeſſed of the electricity contrary to that of the powder."

It is, however, proper to remark with reſpect to this kind of excitation, that the production of the electricity is in ſome meaſure due to the friction ; for in the act of pouring any ſubſtance in powder from a plate, a veſſel, &c. a degree of friction between the latter and the former muſt neceſſarily take place.

Contact, or *juxtapoſition*.—That the mere contact of two perfect conductors would generate, or excite electricity, is a diſcovery of a very late date. Mr. Cavallo ſeems to have been the firſt who proved that by dropping a piece of metal upon another, a ſlight degree of electricity was thereby produced. (See the 4th edition of his Treatiſe on Electricity, publiſhed in 1795, third vol. Experiments on Metallic Subſtances.) Mr. Bennet alſo, independent of Mr. Cavallo's experiments, ſeems to have a claim to this diſcovery. The electricity thus produced was ſo very ſlight, that it could only be diſcovered by the niceſt methods ; but it was the forerunner of a moſt aſtoniſhing diſcovery. In ſhort Mr. Volta, by repeating the contact of metallic ſubſtances, and at the ſame time expoſing them to the action of a ſaline ſubſtance, produced a moſt powerful electrical inſtrument, which has opened a new field of ample and promiſing aſpect, and has furniſhed the chemical philoſopher with the moſt active engine of decompoſition.

This, and the other modes of excitation that have been mentioned ſubſequent to it, *viz.* by means of ſolution, or efferveſcence, and by the action of the animal body, cannot be well explained, nor thoroughly underſtood, without a full, hiſtorical, and circumſtantial account of that new and admirable branch of electricity, which is now commonly called *Galvaniſm ;* but which in juſtice ought rather to be called *Voltaiſm ;* and as it would be uſeleſs to fill this Cyclopædia with repetitions, we muſt refer our readers to the articles of the two laſt mentioned denominations, wherein thoſe other modes of excitation are particularly deſcribed.

EXCITATION *of Heat*.—The temperature of bodies is raiſed either by the approach of a body hotter than themſelves, or by the extrication of heat from the bodies themſelves, occaſioned by ſome particular action or diſpoſition. The former of theſe methods of elevating the temperature is a mere communication of heat ; for that principle continually tends to diſperſe itſelf amongſt ſurrounding bodies, until they all acquire the ſame degree of temperature. The latter is called the *excitation* of heat, ſince an elevation of temperature takes place amongſt bodies which were not hotter than the ſurrounding bodies a ſhort time before. Thus, when a perſon ſtands before a common fire, heat is ſaid to be communicated to him, but with reſpect to the fire itſelf, the heat is ſaid to be excited, or produced by that particular decompoſition of fuel which is called combuſtion. Thus alſo heat is excited by friction, by the mixture of water with ſulphuric acid, and by a great many other means; but it is communicated by the rays of the ſun.

The means by which various degrees of ſenſible heat are produced and communicated, are not more than eight; *viz.* 1. Animal heat, or that power in animals which keeps them warm, and enables them to communicate heat to other bodies. 2. Compreſſion. 3. Friction, or percuſſion of hard bodies. 4. Electricity. 5. Mixture. 6. Fermentation, or putrefaction. 7. The ſun's rays; and, 8. The inflammation of fuel. However, by excluding the conſideration of the ſun's rays for reaſons already aſſigned; by comprehending animal heat, fermentation, and inflammation under the general denomination of decompoſition; and by referring the action of electricity to friction; the various modes of exciting heat, which demand our conſideration in the preſent article, may be reduced to four; namely, compreſſion, friction, mixture, and decompoſition, and even this number may be diminiſhed by two, ſince, as it will appear in the ſequel, both friction and mixture may be comprehended under the head of compreſſion; for in theſe two caſes the excitation of heat ſeems to be occaſioned by the compreſſion or concentration of the integrant parts. We ſhall, however, for the ſake of perſpicuity, treat diſtinctly of the above-mentioned four modes.

The flattening or ſtretching of metallic ſubſtances, whether it be effected by means of the hammer, or ſcrew preſſes, or flattening mills, or wire drawing, or any other ſuch like means, is conſtantly attended with an excitation of heat, and a compreſſion of the metallic ſubſtance. The former of theſe effects is perceived by the feel, or, more accurately, by the thermometer; the latter by an increaſe of ſpecific gravity in the ſubſtance that has been operated upon. Not only the metals, but all other ſubſtances that are ſuſceptible of compreſſion, ſuch as wood, cotton, the aerial fluids, &c. are likewiſe heated by the ſame means. On the other hand, water, hard ſtones, and all ſuch bodies as cannot be condenſed into a ſmaller ſpace, at leaſt not in any conſiderable degree, will not be heated by the above-mentioned means.

The heat, which is thus excited, differs in degree according to the nature of the ſubſtance, the violence of the preſſure, and the quickneſs of the operation; thus a metallic ſubſtance, powerfully and quickly compreſſed, becomes hotter than a piece of wood ſimilarly treated, and hotter than if it were preſſed gently or ſlowly; for with a gentle preſſure little heat is excited, and when the preſſure is applied ſlowly, the heat is diſſipated nearly as faſt as it is excited.

A dexterous blackſmith, by giving a dozen or twenty ſmart ſtrokes with a hammer, to the extremity of a ſlender iron rod upon an anvil, will render that extremity of the rod viſibly red-hot, even in the day light; and this is the way by which ſeveral blackſmiths light the fire of their forges when they go to work in the morning. With reſpect to this operation, Dr. Black, in his Lectures, remarks, that the ſame extremity of the iron rod cannot be rendered red-hot a ſecond time by hammering, unleſs it be firſt annealed, or ſoftened in the fire. "On account," he ſays, "of this and other facts, I began to ſuſpect that malleability and ductility of metals depend on a certain quantity of latent heat exiſting in them, which being extricated by hammering, the metals remain rigid, and require to be placed in the fire or annealed, in order to recover that latent heat."

A mixture of oxygen and hydrogen gaſes, if compreſſed, takes fire, and explodes with great violence. The mechanical condenſation of vapour, and of all the aerial fluids, is attended with a conſiderable elevation of temperature. The condenſation of common air excites a conſiderable degree of heat, and, when quickly performed, it fires a variety of combuſtibles, ſuch as cotton, charcoal previouſly warmed, tinder, &c.; and upon this principle a curious inſtrument has of late been contrived, by which a candle or fire may be lighted. It is nothing more than a ſmall ſyringe, or little condenſer, about ſix inches long, and not much above a quarter of an inch in diameter, (meaning the diameter of its cylindrical cavity.) It has a piſton, the rod of which comes out at one end, and a ſtop-cock at the other end; this ſtop-cock is not perforated quite through, but only little more than half way, ſo that its cavity may either be expoſed to the external air, or it may be turned towards the cylindrical cavity of the ſyringe. The operation is performed in the following manner: the piſton is firſt drawn out as far as the extremity of the ſyringe, a little bit of *amadue*, (more commonly known by the name of German tinder,) is placed into the cavity of the ſtop-cock, which is afterwards turned towards the cylindrical cavity of the ſyringe; this done, the piſton is puſhed in quickly and forcibly, with one ſmart ſtroke, by which means the ſudden condenſation of the air excites a degree of heat ſufficient to ſet fire to the tinder; and in fact if the ſtop-cock be turned outwardly immediately, after having puſhed the piſton in, the tinder will be found burning, and a match may be lighted by it.

From a general conſideration of the effects of compreſſion, it appears that the caloric, or that principle to which the effects of heat are attributed, is contained within the pores of other bodies, ſomewhat like water in the cavities of a ſponge, and that by compreſſing the body, part of that caloric is diſengaged, and becomes ſenſible heat. Thus when a mixture of oxygen and hydrogen gaſes is quickly and forcibly condenſed, that operation forces the gaſes to abandon a quantity of caloric, which becomes ſenſible heat, and as it cannot be diſſipated immediately, raiſes their temperature to a degree ſufficient for their inflammation. This explanation is corroborated by the converſe of the above operation, *viz.* by expanſion; for when gaſes are expanded, they abſorb an additional quantity of heat, which does not raiſe their temperature.

Friction is well known to excite heat, the degree of which differs in proportion to the nature of the bodies concerned, and the force which is employed. This effect of friction is ſo commonly experienced, and ſo generally uſed, as to require but little illuſtration. Rubbing the hands againſt each other, or againſt any part of the body in order to excite heat, is a general practice. Filing, turning, grinding, ſtriking a piece of ſteel againſt a flint, the motion of the axles of wheels in their holes, &c. are common and well-known inſtances of friction, which excite heat. In theſe caſes the conſideration of two remarkable circumſtances forcibly lead us to conclude, that the heat is excited by the compreſſion of the parts of the bodies concerned. One of the circumſtances alluded to is, that compreſſion is the neceſſary conſequence of friction; the other is, that ſuch ſubſtances as are not compreſſible, or the compreſſibility of which is next to nothing, cannot be heated by means of friction.

Thus Dr. Irvine ſays, in his Lectures, "The moſt violent agitation of ſimple fluids, ſuch as water or mercury, will not ſenſibly affect the thermometer. Heat is produced by agitation on thoſe fluids which are compound, and whoſe ſtate of exiſtence is changed by the agitation; ſuch as milk, and the ſolution of certain ſalts in water."

It is aſſerted in Nicholſon's Journal for June 1808, that

Dr. Joſeph Read found that by agitating water in a tin veſſel, or in a glaſs one for a few minutes, the temperature of that fluid was raiſed about eight degrees, as it appeared from a thermometer left in it all that time. We are, however, ſtrongly inclined to ſuſpect that this apparent reſult was owing to ſome fallacy in the mode of conducting the experiment.

It ſeems, therefore, moſt probable, that friction produces a compreſſion, and that the caloric is expelled from the bodies concerned, ſo as to become ſenſible heat, in conſequence of that compreſſion.

The greateſt opponent to this hypotheſis is count Rumford, who inſtituted ſome capital experiments, which are deſcribed at large in the Philoſophical Tranſactions, and in which he ſucceeded to ſet a quantity of water actually a boiling by the friction of metal againſt metal. In ſhort, the metal ſubmitted to friction was encompaſſed by water, and air was carefully excluded from the ſurfaces in motion; yet the water became hot, and was kept boiling a conſiderable time. In this experiment the only obvious ſource of caloric, from without, as the count imagines, was through the borer employed to produce the friction; if it be true, that the water could not at the ſame inſtant be in the act of giving out and receiving heat. Mr. Wm. Henry (Tranſ. of the Mancheſter Society, vol. v. p. 2.) reaſoning upon this experiment of count Rumford, ſays, "I cannot admit that the argument is demonſtrative in proving the evolved caloric not to be derived from external ſubſtances; for no abſurdity is implied in ſuppoſing that a body may be receiving caloric in one ſtate, and giving it out in another." Thus theſe gentlemen ſeem to exclude the action of the compreſſion between the metallic bodies, which is occaſioned by the friction, and upon which the whole effect ſeems moſt probably to depend.

With reſpect to this excitation of heat by means of friction, two uſeful practical conſiderations naturally occur; *viz.* to determine which kinds of friction are capable of producing the greateſt degree of heat, and in what manner the heat which ariſes from the friction of the parts of machinery in general, may be prevented.

The production of heat, and of actual fire, by the friction of wood againſt wood, ſeems to be the firſt that occurs to the human being, ſince the materials neceſſary for it are to be met with every where, and do not require any previous preparation, excepting a trifling adaptation of ſhape. In fact all rude nations that have any notion of fire, light their fires by this means. For this purpoſe, a piece of wood is laid flat nearly in an horizontal ſituation, and another ſlender piece of wood is rubbed with one extremity backward and forward over the ſurface of the former, until it excites heat enough to ſet fire to the duſt that has been abraded from the wood itſelf by the friction. Otherwiſe a blunt pointed piece of wood is held perpendicularly over an horizontal piece, with its point in a little cavity on the ſurface of the latter, and is worked therein, like a drill, by rolling it between the hands of the operator, after the manner of a chocolate mill. Though this operation may at firſt ſight appear to be eaſy and ſimple, and though it be readily performed by the individuals of rude nations; yet certain it is that the practice of it is not eaſily acquired; and in fact there are very few perſons in Europe who are able to ſucceed in it. Profeſſor Bartholdi ſays, that the beſt kinds of wood for this purpoſe are, box-wood rubbed againſt mulberry, or laurel againſt poplar, or againſt ivy. But the uſe of this mode of exciting heat amongſt all civilized nations is ſuperſeded by the incomparably eaſier, and much more effectual method, of ſtriking a piece of ſteel againſt the edge of a ſiliceous ſtone. In this operation ſmall particles of the ſteel are violently compreſſed and ſcraped off in an ignited ſtate, ſo as to fire tinder, gun-powder, &c. The very common and general uſe of this method, for domeſtic conveniency, for gun-locks, &c. renders any farther deſcriptions of it perfectly uſeleſs.

We have ventured to refer the excitation of heat by electricity, to friction, in conſideration that electricity does not excite any heat, unleſs it is actually paſſing through bodies, which in ſome meaſure obſtruct its free paſſage. But we muſt refer the reader for the farther conſideration of this matter to the articles which relate to electricity.

It is a matter of great importance in mechanics to prevent, or, at leaſt, to diminiſh the heat which is excited by the friction of the parts of machinery in general; and for this purpoſe the common practice is to interpoſe ſomething of a lubricating quality between the contiguous parts of machines, *viz.* ſomething which may hinder the too intimate contact of the parts, and whoſe particles are eaſily ſeparated from each other. On various conſiderations olive oil has been found ſuperior to any thing elſe in metallic machinery, and eſpecially in watch or clock-work, when ſteel works in metal or in hard ſtone. Where wood and metals work againſt each other, hog's lard, or mutton-ſuet or ſuch other fat or greaſe, is moſtly uſed; and when wood works againſt wood, then the powder of black lead is found to be the moſt uſeful.

The heat which is excited by the mixture of certain bodies, comes next under conſideration: the inſtances of this kind are very numerous, and different degrees of heat may be excited by this means, as far as actual inflammation. The following are ſelected. If ſpirit of wine be mixed with water, the mixture will inſtantly become hot enough to be perceived not only by means of the thermometer, but likewiſe by the mere application of the human hand. This heat will be gradually diſſipated, ſo that in a few minutes' time that mixture will be found to have acquired the temperature of the ſurrounding bodies. On mixing a quantity of the ſtrongeſt ſulphuric acid with an equal quantity of water, a degree of heat is excited which exceeds that of boiling water. If a mixture of nitric and ſulphuric acids be poured upon an inflammable eſſential oil, ſuch as oil of cloves, oil of turpentine, &c.; the latter is thereby ſo heated as to burſt out in flames. Water mixed with quick-lime excites a conſiderable degree of heat. There is a kind of earth found in Derbyſhire, which is called *black-wad.* If a quantity of this earth, as about half a pound or more of it, be ſprinkled over with linſeed oil, and be then left undiſturbed, and expoſed to the air, about an hour after it will be found in a ſtate of incandeſcence, burning ſomewhat like ſmall coal.

In all the caſes of the excitation of heat by the mixture of fluids, two remarkable circumſtances deſerve particular conſideration. One is that the heat will be excited only when the fluids have a chemical action upon each other, ſuch as between acids and water, ſpirituous liquors and water, &c.; whereas, if oil be mixed with water, or water with quickſilver, no heat will be excited, becauſe no real mixture will take place among theſe bodies. The other circumſtance is, that whenever heat is excited by the mixture of fluids, an incorporation, or a concentration of the ſubſtances is obſerved; for it is always attended with a diminution of bulk. Thus a pint of alcohol and a pint of water, mixed together, will meaſure leſs than two pints. Theſe circumſtances ſeem to indicate, that the affinity, or the mutual attraction of the particles of the bodies concerned, occaſions a kind of compreſſion, in conſequence of which a certain part of the caloric is forced out, and becomes ſenſible heat.

The fourth cauſe of the excitation of heat is decompoſition; and under this head we muſt comprehend the origin of animal heat, fermentation, putrefaction, combuſtion, and all other proceſſes in which the heat is manifeſtly excited in conſequence of the decompoſition of compound bodies. But as theſe proceſſes will be found treated at large under the articles of their peculiar denominations; we ſhall here only add a few remarks on the heat which is produced by decompoſitions in general. In ſhort it ſeems that the caloric, like ſeveral other principles, enters more or leſs into the formation of compound bodies, and that in the decompoſition of theſe bodies, where certain principles are ſet at liberty, and other new combinations enſue, the caloric alſo undergoes its changes; *viz.* it is expelled from certain bodies, and is either ſet entirely at liberty ſo as to become ſenſible heat, or is partially reabſorbed, in which latter caſe but little heat is manifeſted. This liberation of caloric is ſometimes effected ſlowly, as in the proceſs of animal life, in fermentations, &c. or it proceeds ſo quickly and abundantly, as to occaſion actual inflammation. By the concurrence of various favourable circumſtances it happens, not unfrequently, that decompoſitions and ſpontaneous inflammations take place among bodies, which, in general, are not capable of producing ſuch phenomena. Thus, vegetable ſubſtances that have undergone torrefaction, being kept in ſacks of cloth in contact with the ambient air, as coffee, the meal of grain, French beans, &c. have ſometimes been known to take fire. The like effect is alſo produced by the generation of ſulphurated and phoſphorated hydrogen gas. The cauſe of ſubterraneous fires and volcanoes has in great meaſure been attributed to the decompoſition of pyrites, or metallic ſulphurets, buried in the interior of the earth. Theſe maſſes of pyrites are decompoſed by the contact and concurrence of water and air; and the decompoſition is always accompanied by a great extrication of caloric, and a diſengagement of a very inflammable gas, called *ſulphurated hydrogen gas*. This gas is inflamed at an elevated temperature, and communicates the inflammation to other combuſtibles that may be at hand.

With reſpect to the heat which is produced in combuſtions, ſeveral queſtions of economical uſe may be aſked, ſuch as the determination of the cheapeſt and moſt economical mode of employing fuel, the method of preventing the diſſipation of heat, &c. but theſe particulars will be found under the articles FIRE, FUEL, and HEAT.

EXCITEMENT, in Dr. Browne's ſyſten of *Medicine*, nearly ſynonymous with life. See EXCITABILITY.

EXCLAMATION, or ECPHONESIS, in *Rhetoric*, a figure, wherein, by raiſing the voice, and uſing an interjection either expreſsly or underſtood, we teſtify an uncommon ardour, commotion, and paſſion of mind; and expreſs the magnitude of the thing, or the importance of the occaſion.

Such is, "O heavens! O earth!" &c. ſuch alſo is that of Cicero againſt Cataline: "O times! O manners! this the ſenate knows, the conſul ſees—and yet he lives! Lives, ſaid I? nay, and comes into the ſenate!"

In Engliſh the interjections O! or oh! alas! or good God! are generally adjoined in an exclamation. In Latin they uſe O! heu! eheu! ah! vah! pro ſuperi! pro ſuperûm atque hominum fidem!" Sometimes, however, the interjection is underſtood, as, Woe is me! Miſerum me! hoccine ſæculum!

Cicero uſes this figure to expreſs a variety of paſſions. It often denotes reſentment or indignation. Thus, after his return from baniſhment, he exclaims, (*Pro Sext.* c. 12.) "O mournful day to the Senate and all good men; calamitous to the ſtate, afflictive to me and my family; but glorious in the view of poſterity!" At other times it is uſed to expreſs diſdain or contempt. Thus, ſpeaking of Pompey's houſe, which was bought by Mark Antony, he ſays, (Philipp. II. c. 12.) "O conſummate impudence! Dare you go within that houſe! Dare you enter the venerable threſhold, and ſhew your audacious countenance to the tutelar deities which reſide there?" It is no leſs adapted to expreſs grief. Thus, Cicero ſays of Milo, (Pro Milone, ſub fin.) "O that happy country, which ſhall receive this man! ungrateful this, if it baniſh him! miſerable, if it loſe him!" It alſo ſerves to expreſs admiration, as when Cicero, in compliment to Cæſar, ſays, (Pro Ligur. c. 2.) "O admirable clemency! worthy of the greateſt praiſe, the higheſt encomiums, and moſt laſting monuments!" It has its uſe alſo in ridicule and irony. Thus Cicero, in his oration for Balbus, deriding his accuſer, exclaims, "O excellent interpreter of the law! maſter of antiquity! corrector and amender of our conſtitution!" The ſacred writers ſometimes uſe it by way of intreaty or wiſh, Pſ. lv. 6., and at other times in exultation and triumph, ſo St. Paul exclaims, (1 Cor. xv. 25.) "O death, where is thy ſting! O grave, where is thy victory!" It is frequently joined, as in ſome of the preceding inſtances, with the figure "Interrogation." It generally follows the repreſentation of the thing which occaſions it; though it is ſometimes uſed to introduce it, and thus it ſerves to prepare the mind by exciting its attention.

EXCLUSION, the act whereby a perſon or thing is excluded, *i. e.* ſhut out or ſet aſide. A crown imports an excluſion from the papacy: he appointed a ſtranger his heir, in excluſion of his own relations.

Great efforts were made towards the cloſe of the reign of king Charles II. to procure a bill of excluſion, for ſetting aſide the duke of York, the king's brother, on account of his being a papiſt. See CROWN.

EXCLUSIONS, in *Mathematics*. The method of excluſions, is a way of coming at the ſolution of problems (in numerical caſes) by previouſly ejecting, or excluding out of conſideration, ſuch numbers as are of no uſe in ſolving the queſtion; whereby, of conſequence, the proceſs may be regularly and judiciouſly abbreviated.

EXCLUSIVE, is ſometimes uſed adjectively, for the force or power of excluding; as, a patent carries with it an excluſive privilege.

Sometimes it is alſo uſed adverbially; as, he ſent him all the Gazettes, from N° 195, to N° 300 excluſive; *i. e.* all between thoſe two numbers, which themſelves were excepted.

EXCLUSIVE *Propoſitions*, are thoſe wherein the predicate ſo agrees with the ſubject, as to agree with no other. See PROPOSITION. *E. gr.* Virtue alone makes nobility: nothing elſe renders a man truly noble.

EXCŒCARIA, in *Botany*, from *excæco, to deprive of ſight*, becauſe, according to Rumphius, the ſailors who firſt landed on the iſlands of the Eaſt Indies, where this tree grows, were greatly incommoded, and ſometimes even entirely blinded, by the acrid juice which ſpirted forth, as they felled the wood for burning. Linn. Gen. 515. Schreb. 677. Juſſ. 390. Gærtn. t. 108. Claſs and order, *Diœcia Triandria*. Nat. Ord. *Tricoccæ*, Linn. *Euphorbiæ*, Juſſ.

Gen. Ch. Male, *Cal.* Catkin cylindrical, covered with florets. *Cor.* none. *Stam.* Filaments three, thread-ſhaped; anthers roundiſh. Female, *Cal.* Catkin as in the male. *Cor.* none. *Piſt.* Germen ſuperior, roundiſh, ſomewhat triangular;

angular; ſtyles three; ſtigmas ſimple. *Peric.* Capſule three-lobed, ſmooth, of three valves, each marked with a furrow, and three cells. *Seeds* ſolitary, ſmooth.

Eſſ. Ch. Male, Catkin naked. Perianth none. Corolla none. Female as in the male. Styles three. Capſule three-lobed. Seeds ſolitary.

E. *Agallocha.* Linn. Sp. Pl. 1451. (Arbor excœcans; Rumph. Amb. v. 2. 237. t. 79, 80.) Native of rocky, dry, and ſandy places about the coaſt in Amboina and other Eaſt Indian iſlands, flowering in January and February, as well as occaſionally at other ſeaſons. It forms a crooked inelegant tree. The *leaves* are alternate, elliptical, bluntiſh, ſmooth, more or leſs waved or bluntly crenate. *Catkins* cylindrical, lateral. *Capſules* the ſize of a pea. The acrid milk with which the tree abounds, cauſes the inhabitants of the countries where it grows to hold it in abhorrence; but Rumphius ſays it is chiefly dangerous to the eyes. The bark, as well as the milk, are uſed in medicine, being powerfully purgative. There ſeems to be no propriety in applying the Greek name αγαλλοχον, from Dioſcorides, to this tree.

How far the Cammetti, Rheede Hort. Malab. v. 5. 89. t. 45, is a diſtinct ſpecies from the above, we have not materials to decide. Its *leaves* are more pointed and leſs diſtinctly waved. Koenig gathered it by the ſea ſide on the coaſt of Coromandel, in low ground, overflowed during the rainy ſeaſon, which does not agree with what Rumphius relates of the foregoing.

Loureiro deſcribes what is probably another ſpecies, by the name of E. *cochinchinenſis*, in p. 612. of his Flora Cochinch. This, he ſays, has beautiful ſhining *leaves*, red underneath, for the ſake of which it is cultivated as an ornamental ſhrub. Its qualities are aſtringent and glutinous, nor did he ever hear of its being hurtful to the eyes.

EXCOMMUNICATION, an anathema, or eccleſiaſtical cenſure, and puniſhment; whereby a heretic is cut off from the ſociety of the faithful, or an obſtinate ſinner from the communion of the church, and the participation of the ſacraments.

This cenſure of excommunication was originally inſtituted for preſerving the purity of the church; but ambitious eccleſiaſtics converted it by degrees into an engine for promoting their own power, and inflicted it on the moſt frivolous occaſions.

The power of excommunication properly belongs to the biſhop; but he may delegate it to any grave prieſt, with the chancellor.

Every excommunication ſhould be preceded by three public admonitions, two days at leaſt diſtant from each other; but this is to be underſtood of excommunications impoſed by the eccleſiaſtical judge; for thoſe impoſed by the law are incurred to all intents and purpoſes the moment the action is committed.

Theſe latter are called excommunications *by the canon*, or *latæ ſententiæ*; and are ſo very numerous, that it would be difficult even for the beſt canoniſts to give an exact liſt of them; there are fifty in the Clementines; twenty in the bull *Cœna Domini*, &c. Wilkins's Mag. Brit. Conc. vol. iv. p. 664. Rebuffe, on the Concordat, reckons up ſixty penalties accruing upon excommunication.

Excommunication is founded on a natural right which all ſocieties have, of excluding out of their body ſuch as violate the laws thereof.

Excommunication is either *major* or *minor*, i. e. *greater* or *leſs*; the firſt, which is that underſtood when we ſay, ſimply, excommunication ſeparates, or cuts off, the delinquent, not only from the ſacraments, but from all communion and fellowſhip with other Chriſtians. The ſecond, or leſſer, only excludes from the participation of the ſacraments.

The greater excommunication, called alſo *ab homine*, is when a prelate, or his deputy, excommunicates any man perſonally, and interdicts him all ſociety with the faithful, all uſe of ſacraments, &c.

In the ancient church, the ſentences of the greater excommunication were ſolemnly promulged four times in the year, with candles lighted, bells tolling, the croſs, and other ſolemnities.

The leſſer excommunication is incurred *pleno jure*, by having any communication with a perſon excommunicated in the greater excommunication. And this too imports a privation of communion, but not an interdiction from entering the church, or having commerce with the faithful.

Anciently, the excommunicated were obliged to procure abſolution from their biſhop, and make ſatisfaction to the church in forty days' time; otherwiſe they were compelled to it by the ſecular judge, by a ſeizure of their effects, impriſonment of their perſons, &c. (See Excommunicato *Capiendo.*) In France they were allowed a whole year.

By an edict of St. Louis, in the year 1228, vaſſals, tenants, &c. were diſpenſed, or freed from the oath of fidelity, homage, &c. they had taken to their lords, or ſuperiors, when excommunicate, till they had made their ſubmiſſion.

In Spain, to this day, a perſon who is not abſolved from his excommunication in a year's time is deemed a heretic. There was a time, when the people were fully convinced, that the bodies of excommunicated perſons, unleſs they were firſt abſolved, would not rot, but remain entire for ſeveral ages, a horrible ſpectacle to poſterity! as is atteſted by Matthew Paris, and other writers. And the Greeks are ſtill of the opinion, and affirm, they have many proofs thereof, as is ſhewn by Du-Cange, from the teſtimony of a vaſt number of authors.

By the laws, an excommunicated perſon was not to be buried, but the body flung into a pit, or covered with a heap of ſtones; which were called *imblocare corpus*. And by the rubric, in the Book of Common Prayer, the burial office ſhall not be read for any that die excommunicated. See Funeral, &c.

In the ancient church, there were diverſe degrees of excommunication. In effect, excommunication did not always import an interdiction of the ſacraments; but frequently, a ſeparation, or kind of ſchiſm, between the ſeveral churches, or a ſuſpenſion of ſpiritual communication between the biſhops. But afterwards the occaſions of excommunications growing more frequent, they began to uſe it with leſs circumſpection and reſervedneſs.

In the ninth century the eccleſiaſtics were continually making uſe of this ſpiritual weapon, to repel any violences or affronts offered them; and time and familiarity rendering offenders more and more obdurate, they proceeded, by degrees, to rigours unknown to antiquity; as the excommunicating of whole families, or provinces; prohibiting the exerciſe of all religion therein; and even accompanying the excommunications with horrible ceremonies, and direful imprecations.

In the tenth and eleventh centuries, the ſeverity againſt the excommunicated was carried to its higheſt pitch: nobody might come near them, not even their own wives, children, or ſervants; they forfeited all their natural legal rights and privileges, and were excluded from all kinds of offices. Thus was an excommunicated king reduced to the condition of a private man. By thus ſtretching the power of the church to extravagance, they rendered it contemptible.' Gregory VII. tempered it a little; exempting the wives and children of excommunicated perſons from incurring excommunication by holding converſation with their huſbands and parents.

To render the excommunicated ſtill more odious, the prieſt was obliged to ſtop, and break off divine ſervice, if an excommunicated perſon entered the church; nothing of which averſion is any where diſcovered in the practice of the primitive church. At preſent we have but little of the terror or reſpect of our forefathers for excommunication; and it is even judged, and proclaimed, an abuſe, whenever impertinently employed.

The form of excommunication in the Romiſh church, as related by Fevret, is to take lighted torches, throw them on the ground with curſes and anathemas, and trample them out under-foot to the ringing of the bells.

“Auctoritate Dei Patris omnipotentis, et Filii, et Spiritus Sancti, et beatæ Dei genetricis Mariæ, omniumque ſanctorum, excommunicamus, anathematizamus, et a limitibus ſanctæ matris eccleſiæ ſequeſtramus illos malefactores, N. conſentaneos quoque et participes; et niſi reſipuerint, et ad ſatisfactionem venerint, ſic extinguetur lucerna eorum ante viventem in ſæcula ſæculorum. Fiat: Amen: Amen: Amen.” Ex Emendat. Leg. Will. Conquæſt.

We have now none of this folly; the ſentence is gravely read, and the perſon remains excommunicated without farther ceremony. See the form of excommunication of the Engliſh church in Concilia M. Brit. et Hib. vol. iv. p. 663, &c.

Petrus Bleſenſis aſſures us, that in England it was anciently the practice only to excommunicate ſuch as had killed an eccleſiaſtic; whereas they were put to death who had killed a layman. But the reaſon was, they held excommunication a greater puniſhment than death.

The cauſes with us are contempt of the biſhop's court, hereſy, neglect of coming to church, and of receiving the ſacrament, incontinency, adultery, ſimony, &c.

But if the judge of any ſpiritual court excommunicates a man for a cauſe of which he hath not the legal cognizance, the party may have an action againſt him at common law, and he is alſo liable to be indicted at the ſuit of the king. (2 Inſt. 623.) With us by the common law an excommunicated perſon is diſabled to do any act, that is required to be done by one that is “probus et legalis homo.” He cannot ſerve on juries, cannot be a witneſs in any court, and cannot bring an action, either real or perſonal, to recover lands or money due to him. (Litt. § 200.) Beſides, if, within 40 days after the ſentence has been publiſhed in the church, the offender does not ſubmit and abide by the ſentence of the ſpiritual court, the biſhop may certify ſuch contempt to the king in chancery; upon which there iſſues out a writ *De* Excommunicato *capiendo*; which ſee.

We have inſtances of biſhops, who have pronounced formal excommunications againſt caterpillars, and other inſects, after a formal juridical proceſs againſt them, wherein thoſe animals were allowed an advocate, and proctor to defend their cauſe. See Exorcism.

Fevret relates divers inſtances of ſuch excommunications againſt rats, mice, and other animals, for infeſting a country. See the form of theſe excommunications in that author, Traité de l'Albus.

In the ancient church there were two different kinds of excommunications in uſe; the one called *medicinal*, whereby perſons convicted of a crime by their own confeſſion, were removed from communion; the other, called *mortal*, was fulminated againſt rebels, who perſiſted obſtinately in their errors and impieties.

The power of excommunicating was lodged in the whole church in general; that is, the biſhops and prieſts had the adminiſtration thereof by and with the conſent of the people, which was practiſed even in St. Cyprian's time. But afterwards they ceaſed to conſult the people about the matter; the biſhop and clergy arrogated the whole power to themſelves. Recourſe, however, might ſtill be had to the ſynod of the province, to judge of the validity of an excommunication.

Excommunication was alſo practiſed among the Jews, who uſed to expel from their ſynagogue ſuch as had committed any grievous crime. See the Goſpel according to St. John, ix. 22. xii. 42. xvi. 2. And Joſeph. Antiq. Jud. lib. ix. cap. 22. and lib. xvi. cap. 2.

The Eſſeni, when excommunicated, durſt not ſo much as receive food at any perſon's hand, for fear of violating their oath, but contented themſelves to live on herbs; inſomuch that they frequently periſhed and died for want. See Joſeph. de Bell. lib. ii. cap. 12.

Godwyn, in his Moſes and Aaron, diſtinguiſhes three degrees, or kinds, of excommunication among the Jews. The firſt he finds intimated in St. John ix. 22. The ſecond in St. Paul Epiſt. 1 Cor. v. 5. And the third, in the 1ſt Ep. to Corinth. xvi. 22. See Niddui.

The rule of the Benedictines gives the name excommunication to the being excluded from the oratory, and the common table of the houſe in our inns of court called *diſcommoning*. This was the puniſhment of ſuch monks as came too late.

Excommunication, or a being ſecluded, or cut off from a participation in the myſteries of religion, was alſo in uſe under paganiſm.

Such as were thus excommunicated were forbidden to aſſiſt or attend at the ſacrifices, or to enter within the temples; and were afterwards delivered over to the dæmons and furies of hell, with certain imprecations; which was called among the Romans, *diris devovere*. See Execration.

The Druids, among the ancient Britons and Gauls, likewiſe made uſe of excommunication againſt rebels; and interdicted the communion of their myſteries to ſuch as refuſed to acquieſce in their deciſions. See Druids.

That this is the true origin of the extenſive and horrid influence of the European and papal excommunication, will appear evident by the following paſſage of Cæſar, De Bello Gallico, lib. vi. cap. 13. “Si qui aut privatus aut publicus Druidum decreto non ſtetit, ſacrificiis interdicunt. Hæc pœna apud eos eſt graviſſima. Quibus ita eſt interdictum, in numero impiorum et ſceleratorum habentur, ab iis omnes decedunt, aditum eorum ſermonemque defugiunt, ne quid ex contagione incommodi accipiant; neque iis petentibus jus redditur, neque honos ullus communicatur.”

EXCOMMUNICATO Capiendo, ſo called from its effects, or *Significavit*, thus denominated from the biſhops' certificate, a writ directed to the ſheriff, for the apprehenſion of one who ſtands obſtinately excommunicated the ſpace of forty days.

Such a one not ſeeking abſolution, hath, or may have, his contempt certified into the chancery; whence this writ iſſues for taking him up and impriſoning him in the county gaol, without bail or mainprize, until he is reconciled to the church, and ſuch reconciliation is certified by the biſhop.

Excommunicato *Deliberando*, is a writ directed to the under ſheriff, for the delivery of an excommunicated perſon out of priſon; upon certificate of the ordinary of his conformity to the eccleſiaſtical juriſdiction. F. N. B. 62.

Excommunicato *Recipiendo*, is a writ whereby perſons excommunicated, being for their obſtinacy committed to priſon, and unlawfully delivered from thence before they have given ſecurity to obey the authority of the church, are commanded to be ſought for and laid up again.

EXCORIATION, in *Surgery*. A part is ſaid to be excoriated, when it is deprived of its cuticle, by reaſon of inflammation, the action of irritating matter, or of ſtimulating ſubſtances, &c. applied to the ſkin.

Very ſuperficial ulcerations are, alſo, frequently denominated excoriations.

In conſequence of inattention to cleanlineſs, and not occaſionally waſhing away the ſebaceous ſecretion, which is naturally produced under the prepuce, the matter acquires an irritating acrid quality, brings on inflammation all round the corona glandis, followed by extenſive excoriations and ſuppuration. This ſort of caſe is ſeriouſly annoying to the patient, on account of the violent itching, and troubleſome ſoreneſs, which always attend the complaint. The diſorder has ſometimes been named the *falſe gonorrhœa*, and the patient is often rendered very uneaſy in his mind by an apprehenſion of the affection being venereal. Indeed, ignorant and careleſs practitioners have occaſionally miſtaken mere excoriations for chancres, and, quite improperly, have preſcribed a courſe of mercury.

The proper treatment conſiſts in waſhing away all the acrid ſecretion under the prepuce with ſome ſoap-ſuds; injecting under the ſame part, four or five times a day, the ſaturnine lotion; and keeping linen, wet with this application, round the extremity of the penis. The excoriations, if very bad, are to be dreſſed with the ſaturnine ointment. The prepuce, if much ſwelled, and in a ſtate of phymoſis, ſhould have two or three leeches put upon it; but the principal means of cure is attention to keeping the parts clean, and tenderly waſhed with plenty of ſoap once or twice a day. As in all other caſes of inflammation the bowels ought to be kept open.

Excoriation of the nipples is a moſt diſtreſſing complaint. It is more common in the firſt, than the ſubſequent nurſings, and when independent of any diſeaſe in the child's mouth, is owing to the irritation occaſioned by the ſuction.

In many inſtances, a cure may be effected by bathing the parts with a little port wine, or brandy. A more effectual remedy is ſaid to be the tincture of opium.

EXCORTICATION, the act of ſtripping off the cortex or bark from any thing; called alſo decortication.

EXCREMENT, in *Chemiſtry*. See Feces.

Excrement, in *Phyſiology*, is the reſidue of our food, after the nutritious particles have been extracted from it, and it has undergone certain changes by its reſidence in the large inteſtine. See Digestion.

Excrement is alſo attributed, by way of analogy, to plants. Thus gums, diverſe juices, balms &c. iſſuing ſpontaneouſly from their reſpective trees, are ſometimes called excrements.

EXCRESCENCE, in the language of *Surgery*, implies a preternatural protuberance, or any morbid growth, which *projects out of* the ſubſtance or ſurface of a part. When the diſeaſe is involved in the ſurrounding fleſh, though it may be attended with a conſiderable ſwelling, it does not rank as an excreſcence, which word eſſentially ſignifies that the tumour, or whatever the diſeaſe is, *grows out of* the part. Funguſes, polypi, and warts of all kinds, are very often, and with ſtrict propriety, denominated excreſcences.

Excreſcences, of the nature of warts, are particularly apt to grow about the anus. Some of them are generally regarded by ſurgical authors as venereal complaints, becauſe they ſometimes get well under a courſe of mercury. This, however, is a very fallacious criterion of a diſeaſe being ſyphilitic; for mercury is a cure for numerous affections beſides venereal ones. Some ſurgeons have doubted whether there is any ſuch thing as a really venereal excreſcence; and as far as our obſervations extend, all thoſe warty growths which ariſe about the anus and perinæum, and are commonly reputed to be of a ſyphilitic nature, may be cured upon the ſame principles as any other ordinary tumours, not of a ſpecific kind.

Excreſcences in general, not being original parts of the body, are known to be weak in the vital power, and to be incapable of bearing the action of ſuch ſtimulating applications as would not deſtroy a part, which may be ſaid to enter into the natural compoſition of the body. Hence it is, that ſprinkling on warty excreſcences a powder, conſiſting of ſavin and ærugo æris, in equal proportions, generally effects a cure. The ſwellings are partly diminiſhed by abſorption, and partly by ſloughing. We have never ſeen about the anus any excreſcences which could withſtand this application.

But the plan which we particularly recommend to be adopted, when ſuch excreſcences are large and numerous, as they frequently are, is to remove them at once with a knife, or a pair of ſciſſars. When they grow from a narrow neck, their deſtruction might be accompliſhed by tying them with a ligature. The latter method, indeed, is often practiſed by ſurgeons who are fearful of hæmorrhage, or whoſe patients have a remarkable dread of a cutting inſtrument, even in caſes in which the object could be fulfilled much more eaſily, and with leſs pain, by means of exciſion; that is to ſay, in examples in which the baſe of the ſwellings is rather broad. Indeed, where the excreſcences are connected with the ſkin by a wide root, the mode of removing them with a ligature becomes exceedingly troubleſome and painful; for the practitioner is firſt under the neceſſity of introducing, through the centre of their baſe, a needle armed with a double ligature. The needle being cut off, one ligature is then to be firmly tied over one ſide of the root of the tumour, and the other over the oppoſite one. In this manner the ſupply of blood to the excreſcence is ſuppreſſed, and the part ſloughs away. Sometimes when the baſe of the diſeaſe is very broad, and the ligature has not been applied with due tightneſs, it becomes neceſſary to apply another one, the doing of which is attended with as much, if not more, pain than the firſt operation.

Upon the whole, when the excreſcences are ſmall, we prefer ſtimulating them with the powder of ſavin and ærugo æris; when they are large, we recommend extirpating them with a cutting inſtrument.

EXCRETION, from *excerno*, *I throw off*, or *ſeparate*, is the ſeparation of any ſuppoſed noxious matter from the blood in any of the organs of the animal body. The proceſs itſelf is not eſſentially different from that of ſecretion. But the latter term is applied to thoſe ſubſtances which, when formed, are applied to uſeful purpoſes in the animal economy. Thus the mucus of mucous membranes imparts to them a neceſſary moiſture, and defends them from the action of the foreign matter which comes in contact with them; the ſerous exhalation of ſerous membranes preſerves them conſtantly ſmooth and poliſhed, and therefore in a fit ſtate for their oppoſed ſurfaces to move without any obſtacle, &c. The excretions are matters ſuppoſed to be noxious to the body, and to be ſeparated on that account, as the urine, bile, perſpiration, &c. The matters voided from the large inteſtine, conſiſting of the reſidue of our food, are often called the alvine excretions.

EXCRETORY, is applied to certain little ducts or veſſels in the fabric of the glands.

Excretory ducts are the tubes through which the humours ſeparated in the ſeveral glands are emitted or diſcharged out of the gland, into ſome convenient receptacle or emunctory.

A capillary artery, to which a capillary vein is joined, with an excretory duct, convolved or wound together, make up the body of the glands, the organs of ſecretion. The excretory ducts ſpring from the extremities of the arteries and veins, and carry off a liquor ſeparated from the blood. Drake.

The lymphatic glands have either lymphæducts for their excretory ducts, or lacteal veſſels, as in the meſentery. Idem.

EXCURSION, in *Aſtronomy*. See ELONGATION.

EXCURSION, *circles of*. See CIRCLES.

EXCUSABLE HOMICIDE. See HOMICIDE.

EXCUSATI, in *Church Hiſtory*, a term uſed to denote ſlaves, who, flying to any church for ſanctuary, were excuſed and pardoned by their maſters; but theſe were obliged to take an oath to that purpoſe, before they could have them again; and if they broke the oath, they were puniſhed and fined as perſons guilty of perjury.

EXDORF, in *Geography*, a town of Germany, in the county of Henneberg; 7 miles S.E. of Meinungen.

EXE, a river in England, has its origin among the wild eminences of Exmoor, in the weſtern corner of Somerſetſhire, and after uniting with the Barle, enters the confines of Devonſhire, near Exe bridge; thence flowing near Bampton, it ſinks into a rich wooded vale, and paſſing Tiverton, has its current increaſed by the ſtreams of the Loman. Soon after, the Creedy, from Crediton, in the north-weſt, and the Culm, or Columb, from Cullumpton, in the north-eaſt, intermingle their waters with the Exe, and the vale expanding, opens into a beautiful plain, encircled by towering eminences, clothed with wood. Paſſing Exeter, the river proceeds through a fine range of meadows to Topſham, where meeting the tide, and ſuddenly widening to an extent of more than a mile, it becomes navigable for veſſels of ſeveral hundred tons burthen. Hence ſpreading into a grand eſtuary, it rolls onward; but its direct courſe being impeded by a vaſt ſand-bank, called the Warren, it winds to the eaſtward, and flows into the Britiſh channel near Exmouth, its whole courſe being about 60 miles. See CANAL.

EXEA DE LOS CAVALLEROS, an inconſiderable town of Spain in the province of Aragon, ſeated between two rivulets, in the northern part of the province. Its ſurname commemorates the bravery of ſome French and Gaſcogne cavalry, when Alphonſo I. king of Aragon, took it from the Moors. N. lat. 42° 6′. W. long. 1° 9′.

EXEAT, in *Church Diſcipline*, a Latin term uſed for a permiſſion which a biſhop grants a prieſt to go out of his dioceſe; or an abbot to a religious, to go out of his monaſtery.

The word is alſo uſed in ſeveral great ſchools for leave given a ſcholar or ſtudent to go out. His maſter has given him an exeat.

EXECRATION, EXECRATIO, among the *Ancients*, a kind of puniſhment, conſiſting of direful curſes and marks of infamy. Livy relates an inſtance of it, which was uſed againſt Philip king of Macedon, by the Athenians. A general aſſembly of the people being called, they made a decree, that all the ſtatues and images of that king, and of all his anceſtors, both of the male and female ſex, ſhould be demoliſhed, and their very names raſed; that all the feſtivals, ſacred rites, prieſts, and whatever elſe had been inſtituted in honour of him, ſhould be profaned; that the very place where there had been any monument or inſcription to his honour, ſhould be deteſtable, and that nothing ſhould be ſet up, or dedicated in them, which could be done in clean places; and, laſtly, that the public prieſts, as often as they prayed for the Athenian people, allies, armies, and fleets, ſhould as many times deteſt and execrate Philip, his children, kingdom, land, and ſea forces, and the whole race and name of the Macedonians.

Cornelius Nepos, in his life of Alcibiades, calls it *devotion*.

At the taking or demoliſhing of a city, it was frequent to pronounce direful curſes and execrations upon any perſon who ſhould endeavour to rebuild it; which ſome imagine was the reaſon that Troy could never be raiſed out of its aſhes, though ſeveral perſons attempted it, being devoted to eternal and irreparable ruin by Agamemnon. This ſeems to have been a very ancient cuſtom, and derived from the Eaſtern nations; for we find Joſhua, at the deſtruction of Jericho, to have fixed an imprecation upon the perſon who ſhould rebuild it, which was thought to be accompliſhed in Hiel the Bethelite many ages after. Potter, Archæol. tom. ii. p. 97.

EXECREBRONCHOS, in *Surgery*, from εξεχω, *to abound*, and βρογχος, *a throat*, a term which probably ſignified a ſwelling of the thyroid gland, which affection is now almoſt always named bronchocele.

EXECUTANT, Fr. in *Muſic*, a participle uſed ſubſtantively. A muſician or performer who executes his part in a band, in the ſame ſenſe as concertant implies a performer in a concert. See CONCERTANT, EXECUTER, and EXECUTION.

EXECUTED *Contract*, *Eſtate*, *Fine*, and *Remainder*. See the ſubſtantives.

EXECUTER, *Fr.* to execute, play, ſing, or perform a compoſition, or piece of muſic, in all its parts, whether vocal or inſtrumental, and to let every note and paſſage be heard agreeable to the notation in the ſcore.

As muſic is an object for the ear, it can only be judged by its effects in the execution. Many pieces of counterpoint look correct and learned on paper, which no real judge can hear without diſguſt; and others that look thin, ſimple, and common, which in the execution afford the higheſt pleaſure, by unexpected effects. Vulgar compoſers, attentive to ſymmetry and the filling up all the parts, often appear to be great contrapuntiſts, while they are judged merely by the eyes; and ſuch compoſers often have the addreſs to employ ſo many different inſtruments, and ſuch a number of parts in their muſic, that it is with great difficulty a ſufficient band can be collected to do it juſtice in the execution. Rouſſeau.

EXECUTION, the act of executing, *i. e.* of accompliſhing, finiſhing, or atchieving any thing to be done.

We ſay, the execution of a teſtament; of a law; of a treaty; of a building, or the like.

EXECUTION, in *Common Law*, ſignifies the laſt performance of an act; as of a writ, a judgment, or the like.

EXECUTION *of a judgment*, denotes the putting of the law in force, or it is the obtaining the poſſeſſion of any thing recovered by judgment of law.

This is performed in various ways, according to the nature of the action upon which it is founded, and of the judgment which is had or recovered. If the plaintiff recovers in an action real or mixed, whereby the ſeiſin or poſſeſſion of land is awarded to him, the writ of execution ſhall be an *habere facias ſeiſinam*, or writ of ſeiſin, of a freehold; or an *habere facias poſſeſſionem*, or writ of poſſeſſion, of a chattel intereſt. (Finch. L. 470.) Theſe are writs directed to the ſheriff of the county, commanding him to give actual poſſeſſion to the plaintiff, of the land ſo recovered; in the execution of which the ſheriff may take with him the *poſſe comitatus*, or power of the county, and may juſtify breaking open doors, if the poſſeſſion be not quietly delivered. But if it is peaceably yielded up, the delivery of a twig, a turf, or the ring of the door, in the name of ſeiſin, is ſufficient execution of the writ. Upon a preſentation to a benefice recovered in a *quare impedit*, or aſſiſe of *darrein preſentment*, the execution is by a writ *de clerico admittendo;* directed not to the ſheriff, but to the biſhop or archbiſhop, and requiring him to admit and inſtitute the clerk of the plaintiff. In other actions, where the judgment is, that ſomething ſpecial be done or rendered by the defendant, then, in order to compel him ſo to do, and to ſee the judgment executed, a ſpecial writ of execution iſſues to the ſheriff, according to the nature of the caſe. As, upon an aſſiſe of nuſance, or *quod permittat proſternere*, where one part of the judgment is *quod nocumentum amoveatur*, a writ goes to the ſheriff to abate it, at the charge of the party, which likewiſe iſſues even in caſe of an indictment. (Comb. 10.) Upon a replevin, the writ of execution is the writ *de retorno habendo;* and if the diſtreſs be eloigned, the defendant ſhall have a *capias in withernam;* but on the plaintiff's tendering the damages, and ſubmitting to a fine, the proceſs *in withernam* ſhall be ſtayed. (2 Leon. 174.) In detinue, after judgment, the plaintiff ſhall have a *diſtringas*, to compel the defendant to deliver the goods, by repeated diſtreſſes of his chattels, (1 Roll. Abr. 737. Raſt. Entr. 215); or alſo a *ſcire facias* againſt any third perſon in whoſe hands they may happen to be, to ſhew cauſe why they ſhould not be delivered; and if the defendant ſtill continues obſtinate, then (if the judgment hath been by default or on demurrer) the ſheriff ſhall ſummon an inqueſt to aſcertain the value of the goods, and the plaintiff's damages; which (being either ſo aſſeſſed, or by the verdict in caſe of an iſſue, Bro. Abr. tit. *Damages*, 29.) ſhall be levied on the perſon or goods of the defendant.

Executions in actions, where money only is recovered, as a debt or damages, (and not any ſpecific chattel,) are of five ſorts: either againſt the body of the defendant; or againſt his goods and chattels; or againſt his goods and the *profits* of his lands; or againſt his goods and the *poſſeſſion* of his lands; or againſt all three, his body, lands, and goods. The *firſt* of theſe ſpecies of execution is by writ of CAPIAS *ad ſatisfaciendum*, which ſee. This writ is an execution of the higheſt nature, inaſmuch as it deprives a man of his liberty, till he makes the ſatisfaction awarded. When a defendant is once in cuſtody upon this proceſs, he is to be kept in *arcta et ſalva cuſtodia;* and if he be afterwards ſeen at large, it is an *eſcape*, which ſee; and the plaintiff may have an action thereupon againſt the ſheriff for his whole debt. If a *capias ad ſatisfaciendum* be ſued out, and a *non eſt inventus* is returned thereon, the plaintiff may ſue out a proceſs againſt the bail. The *ſecond* ſpecies of execution is againſt the goods and chattels of the defendant, and is called a writ of FIERI *facias*, which ſee. A *third* ſpecies of execution is by writ of LEVARI *facias*, which ſee. This affects a man's goods and the *profits* of his lands. This writ is now little uſed, the remedy by *elegit* being much more effectual. This writ of *elegit* is the *fourth* ſpecies of execution. Moreover, upon ſome proſecutions given by ſtatute, as in the caſe of recognizances or debts acknowledged on ſtatutes merchant, or ſtatutes ſtaple; (purſuant to the ſtatutes 13 Ed. I. *de Mercatoribus*, and 27 Ed. III. c. 9.) upon forfeiture of theſe the body, land, and goods may all be taken at once in execution, to compel the payment of the debt. This proceſs is the *fifth* ſpecies of execution, and is uſually called an *extent*, or *extendi facias*, which ſee. It is to be obſerved, that all theſe writs of execution muſt be ſued out within a year and a day after the judgment is entered, otherwiſe the court concludes *prima facie*, that the judgment is ſatisfied and extinct; yet, however, it will grant a writ of *ſcire facias*, in purſuance of ſtatutes Weſtm. 2. 13 Edw. I. c. 45. for the defendant to ſhew cauſe why the judgment ſhould not be revived, and execution had againſt him; to which the defendant may plead ſuch matter as he has to allege, in order to ſhew why proceſs of execution ſhould not be iſſued: or the plaintiff may ſtill bring an action of debt, founded on this dormant judgment, which was the only method of revival allowed by the common law. (Co. Litt. 290.) Blackſt. Comm. B. III.

Sir Edward Coke, in his Reports, makes two ſorts of executions; one *final*, another with *a quouſque*, as only tending to an end.

EXECUTION *final*, is that which maketh money of the defendant's goods, or extendeth his lands, and delivers them to the plaintiff; which he accepts in ſatisfaction; and this is the end of the ſuit, and all that the king's writ commands to be done.

EXECUTION *with a quouſque*, is that which only tends to an end; as in the caſe of a *capias ad ſatisfaciendum*, &c.

This is not final; but the body of the party is to be taken, to the intent and purpoſe to ſatisfy the plaintiff; and his impriſonment is not abſolute, but till he doth ſatisfy; ſo that the body is but a pledge for the debt. 6 Rep. 87.

EXECUTION, *Tenant by*. See TENANT.

EXECUTION *of criminals*, muſt be according to judgment; and the king cannot alter a judgment from hanging to beheading, becauſe no execution can be warranted, unleſs it be purſuant to the judgment. (3 Inſt. 52. 211. H. P. C. 252.) But there are ancient precedents wherein men condemned to be hanged for felony, have been beheaded by force of a ſpecial warrant from the king. (Bract. 104. Staundf. 13.) And the king may pardon part of the execution in judgment for treaſon, *viz.* all but beheading. It has been ſaid by ſir Edward Coke, and ſir Matthew Hale, that the king cannot change the puniſhment of the law, by altering the hanging or burning into beheading. But others have thought (Foſt. 270. F. N. B. 244.), and as judge Blackſtone ſays, more juſtly, that this prerogative being founded in mercy, and immemorially exerciſed by the crown, is part of the common law. The court may command execution to be done without any writ; (Finch, L. 478.) though ſometimes execution is commanded by writ. (2 Hawk. P. C. 463.) Judgment belongs to the judge; but the execution may be done by the ſheriff, or his deputy; and an execution cannot be lawfully made by any but the proper officer, whoſe warrant for ſo doing was anciently by precept of the judge under his hand and ſeal; as it is ſtill practiſed in the court of the lord high ſteward, upon the execution of a peer; (2 Hal. P. C. 409.) though in the court of peers in parliament, it is done by writ from the king; and if the ſheriff, or other officer alters the execution, or any other executes the offender, or if he is killed without the authority of law, it is felony. (2 Hawk. ib.) The uſage now is for the judge to ſign the calendar, or liſt of all the priſoners' names, with their ſeparate judgments in the margin, which is left with the ſheriff. As for a capital felony, it is written oppoſite to the priſoner's name, "let him be hanged by the neck;

formerly, in the days of Latin and abbreviation, "ſuſ. per coll." for *ſuſpendatur per collum.* And this is the only warrant which the ſheriff has for ſo material an act, as taking away the life of another. (5 Mod. 22.) Upon this judge Blackſtone obſerves, that it may certainly afford matter of ſpeculation, that in civil cauſes there ſhould be ſuch a variety of writs of execution to recover a trifling debt, iſſued in the king's name, and under the ſeal of the court, without which the ſheriff cannot legally ſtir one ſtep; and yet that the execution of a man, the moſt important and terrible taſk of any, ſhould depend upon a marginal note. The ſheriff, upon receipt of his warrant, is to do execution within a convenient time, which in the country is alſo left at large. In London a more ſolemn and becoming exactneſs is uſed, both as to the warrant of execution, and the time of executing thereof; for the recorder, after reporting to the king in perſon the caſes of the ſeveral priſoners, and receiving his royal pleaſure, that the law muſt take its courſe, iſſues his warrant to the ſheriffs, directing them to do execution on the day, and at the place aſſigned; and in the court of king's bench, if the priſoner be tried at the bar, or brought there by *habeas corpus,* a rule is made for his execution, either ſpecifying the time and place, (State Trials, p. 332. Foſt. 43.) or leaving it to the diſcretion of the ſheriff. And, throughout the kingdom, by ſtatute 27 Geo. II. c. 37. it is enacted, that in caſe of murder, the judge ſhall in his ſentence direct execution to be performed on the next day but one after ſentence paſſed. But otherwiſe, the time and place of execution are by law no part of the judgment, as was held by the twelve judges. (Mich. 10 Geo. III.) Beccaria has well obſerved, (On Crimes, &c. ch. 19.) that it is of great importance, that the puniſhment ſhould follow the crime as early as poſſible; that the proſpect of gratification or advantage, which tempts a man to commit the crime, ſhould inſtantly awake the attendant idea of puniſhment. Delay of execution ſerves only to ſeparate thoſe ideas, and then the execution itſelf affects the minds of the ſpectators rather as a terrible ſight, than as the neceſſary conſequence of tranſgreſſion.

In caſe a man condemned to die, come to life after he is hanged, as the judgment is not executed till he is dead, he ought to be hung up again. (2 Hal. P. C. 412. 2 Hawk. P. C. 463.) For the former hanging was no execution of the ſentence; and if a falſe tenderneſs were to be indulged in ſuch caſes, a multitude of colluſions might enſue. The body of a traitor, or felon, is forfeited to the king by the execution. Execution may be avoided by a *reprieve* or a *pardon,* which ſee reſpectively.

Execution *of decrees,* in *Scots Law,* is effected by diligence, either againſt the perſon, or againſt the eſtate of the debtor. The firſt ſtep of perſonal execution is by letters of horning, which paſs by warrant of the court of ſeſſion, on the decrees of magiſtrates of boroughs, ſheriffs, admirals, and commiſſaries. If the debtor does not obey the will of the letters of horning, within the days of the charge, the charger, after denouncing him rebel, and regiſtering the horning, may apply for letters of caption, which contain a command, not only to meſſengers, but to magiſtrates, to apprehend and impriſon the debtor. All meſſengers and magiſtrates who refuſe their aſſiſtance in executing the caption, are liable *ſubſidiarè* for the debt; and ſuch ſubſidiary action is ſupported by the execution of the meſſenger employed by the creditor, expreſſing that they were charged to concur, and would not. Letters of caption contain an expreſs warrant to the meſſenger, in caſe he cannot get acceſs, to break open all doors, and other lock-faſt places. The law ſecures peers, married women, and pupils, againſt perſonal execution of caption upon civil debts. Such commoners alſo as are elected to ſerve in parliament, are ſecured againſt perſonal execution by the privilege of parliament. No caption can be executed againſt a debtor within the precincts of the king's palace of Holyrood-houſe; but this privilege of ſanctuary afforded no ſecurity to criminals, as that did which was by the canon law conferred on churches and religious houſes. When the perſonal preſence of a debtor, under caption, is neceſſary in any of our ſupreme courts, the judges are empowered to grant him a protection, for ſuch time as may be ſufficient for his coming and going, not exceeding a month. Protection from diligence is alſo granted by the court of ſeſſion, under the late bankrupt ſtatute, when it is applied for, with concurrence of the truſtee, or a certain number of the creditors, as the caſe may require.

Execution, *military,* is the pillage or plundering of a country by the enemy's army.

Execution alſo denotes every kind of puniſhment inflicted on an army by ſentence of a court-martial. This is of various kinds; as tying up to three halberts, and receiving a number of laſhes with a whip compoſed of nine cord-laſhes, and each laſh of nine knots, from the drummer; or running the gantlope through the parade at guard-mounting, drawn up in two lines for that purpoſe. On this occaſion the provoſt marches through with twigs or ſwitches, and every ſoldier takes as many as there are criminals to be puniſhed; the criminal then marches through the two lines, and each ſoldier gives him a hard ſtroke, the major riding up and down, to ſee that the men lay on properly. When a ſoldier is to be puniſhed with death, a detachment of about two hundred men from the regiment to which he belongs forms the parade, and a file of grenadiers ſhoots the priſoner to death. Different nations have different modes of puniſhment. The cat with nine tails is deſigned to puniſh foot-ſoldiers; but dragoons and cavalry-men are generally picketed.

Execution, in *Muſical Performance,* the action of conveying to the ear, by the aſſiſtance of the eye, what has been written in the ſcore. As much muſic is compoſed of many parts ſo interwoven and linked together, that both the time and intonation are very difficult to ſeize, and of which the ſpirit depends more on taſte than notation of ſuch pieces, nothing is ſo uncommon as a perfect execution. The reading of the notes exactly is no great merit, the performer muſt enter into all the ideas of the compoſer, and feel, and make the hearer feel, the fire or pathos of the expreſſion; but above all he muſt be poſſeſſed of a nice and acute ear, always attentive to the effect of the whole. In French muſic the leader muſt be particularly careful to preſs and relax the time according to the taſte of the melody, the power of voice, and the geſticulation of the ſinger; the other parts muſt conſequently be extremely attentive in following him. "The totality of the opera at Paris, where muſic had no other meaſure than the geſtures of the ſinger, muſt, in my opinion, require an admirable muſician indeed to keep all the performers together." N. B. This was written by Rouſſeau near 40 years ago, and at that time little diſputed; but the editors of the late edit. of the Encyc. men of taſte and judgment, will, perhaps, ſay with Moliere, "medicin malgre lui," this may have been ſo formerly, "mais, nous avons changés tout ca."

"If the French," ſays St. Evremond, "compoſe in a bolder ſtyle than formerly by their intercourſe with the Italians, the Italians in their turn have gained by their commerce with the French, by learning of them a more agreeable touching, and perfect execution." Letter to the duke of Buckingham.

The reader (ſays the author of the Lettre ſur la Muſ. Fran.) will, I believe, excuſe me if I wave making any remarks on this paſſage, I ſhall only obſerve, that the French think all the world intereſted about their muſic ; but on the contrary, in three fourths of Italy, Italian muſicians are totally ignorant that there exiſts a muſic in France different from their own.

A facility of reading and performing a ſingle part is likewiſe called, if difficult, execution ; particularly when rapid paſſages are played correctly, and without heſitation, at ſight.

Execution of this kind depends in an eſpecial manner on two things ; the firſt in having a powerful hand and quick eye ; and the ſecond in having read much muſic, and being able to phraſe it at a glance : for while we only look at ſingle notes, we ſhall heſitate in pronouncing them : a great facility of execution is only acquired by uniting them into meaning, and putting the thing itſelf in the place of the ſign. In this manner the memory of the reader of a book is no leſs aſſiſted than by his eyes ; and what he would read with great difficulty in a foreign language, though written or printed with the ſame characters as his own.

Execution, in *Painting*, is a technical term ſignifying the ſtyle and manner in which a painter performs his work : in other words, the mechanical part of the art, as far as relates to the handling of the pencil in laying on the colours of a picture.

It is evident from this definition, that without poſſeſſing it in ſome degree, all knowledge of the other branches of the art is totally nugatory ; to what purpoſe would the theory be made perfect, if no practical means of applying it were underſtood ; but beſides that degree of execution abſolutely requiſite to produce any thing in the ſhape of a picture, it well deſerves to be made an object of particular ſtudy, as its various modes are productive of much utility in the progreſs of a picture. A great deal of the character of many objects in painting depends on the manner in which they are wrought, that is, on the peculiarity of the ſtrokes of the pencil ; ſuch, for inſtance, are all ſkins of beaſts ; feathers of birds ; trees ; various kinds of drapery ; armour, &c. in producing the effects of which, execution will alone go very far, in ſpight of bad form and bad colour. There is a charm in it which few perhaps but painters know, and which, unhappily, too many painters feel and value too highly, and deſert for it qualities of a much more valuable kind ; and are content too often to let their works paſs imperfect, even with the knowledge of their imperfections, rather than diſturb the beauty of clearneſs of touch which they may happen to poſſeſs.

It is indeed a taſk of no eaſy nature fully to obtain this quality, as it requires the utmoſt preciſion of judgment ſo to execute a work of art, that ſpirit and vigour ſhould be maintained, accompanied with ſoftneſs and truth. Without which union the diſplay of it is a vice of art inſtead of an excellence, and damns inſtead of exalting the work.

Knowledge of the general character of the object about to be repreſented is the only foundation of a beautiful, decided, and juſt execution : poſſeſſed of that, the artiſt holds in his hands the maſter-key of the expreſſion of its qualities, and renders its effect without difficulty. Wanting it he produces his work with heavineſs, with bungling, and confuſion.

It has been remarked that the countenances of men ſcarcely differ more than do the characters of their hand-writing, and not far, if at all, ſhort of the variety of either of theſe, is that of the manner in which painters have executed their works. Each man in this alſo has his peculiarity ; no two are ſo exactly alike in the execution of their pictures that an able connoiſſeur would not diſtinguiſh between them, and preſently attribute each to its reſpective author.

This diſcrimination of hands conſtitutes almoſt the tout-enſemble of the knowledge of the hoſt of would-be connoiſſeurs ; and unhappily, too many of them have obtained an influence over the opinions of men well able to teach them in better things appertaining to the arts, if common ſenſe were allowed to rule ; and this merely by having pored over the works of painters to endeavour to aſcertain the diſtinguiſhing characteriſtics of each one's workmanſhip : a ſpecies of knowledge agreeable and uſeful to a certain degree, but of eaſy acquirement, and to which thoſe who have a genuine feeling for the really good and valuable qualities pictures may poſſeſs, ſeldom give ſufficient attention to obtain an extended information in it. The works of good artiſts will force themſelves upon our notice, and after ſufficiently admiring the general effects of beauty, of ſublimity, or character they exhibit ; we naturally ſeek to know by what means or in what manner their various parts are executed, and for the purpoſes of connoiſſeurſhip a ſatisfactory acquaintance ſoon takes place on that head. The works of thoſe whoſe power in art is not ſufficient to attract by thoſe better qualities are ſurely not worthy of that cloſe inſpection which is required to become acquainted with their peculiarities of execution. But the trick of the connoiſſeur dealer is, by ſome fancied reſemblance or ſome ſlight reality of reſemblance, to paſs off an inferior work under the ſanction of a great name ; while, as we have obſerved, if common ſenſe were allowed to rule, the name would add no value to the picture, the tinſel would ſtill glare under the gold, and the bauble be ſoon loſt.

This indiſpenſable portion of the art of painting requires early tuition in order to poſſeſs a ready power over the hand, ſo that it ſhall move freely at the command of the will to effect its deſires. The ſame in fact is the caſe with regard to the acquirement of free execution in any other art, ſuch as muſic, writing, &c. For though our muſcles appear to act merely on our willing that their office ſhould be performed, and without any particular direction of the power of the mind over the particular muſcles which produce the motion, yet, in fact, that immediate influence is applied, although from habit and its extreme rapidity, we are inſenſible of the communication. This is plain when we require the uſe of muſcles, in a direction we are not conſtantly in the habit of uſing them in. For inſtance, a man not accuſtomed to ride, or firſt mounting a horſe, finds it neceſſary to exert all his mental influence to cauſe thoſe muſcles to act which are requiſite to maintain his ſeat on the back of the animal, and the communication of that influence is evidently felt ; but when habit has confirmed him in his ſeat on horſe-back, though thoſe ſame muſcles continue to act when he is mounted, he is unconſcious of conſtraining them to do ſo, the dictates of his will are then ſo inſtantaneouſly excited, that the connection between the exertion of its influence, and its effect is completely unobſervabile.

It is therefore requiſite for men deſirous of making conſiderable progreſs in the practical part of an art, early in life to apply themſelves earneſtly to its attainment. The beſt mode of obtaining it in painting is, by copying the works of thoſe moſt ſkilful in their diſplay of it, taking care at the ſame time to lay in a good ſtore of knowledge of the materials requiſite for the art, particularly (if hiſtorical painting be the courſe intended to be purſued) of the human figure, the foldings of draperies, &c. &c., and after ſome time ſpent in making copies of fine works, to paint from nature herſelf, keeping in view the manner in which the great painters, whoſe works they have imitated, ſaw her productions; obſerving how they diſpoſed of thoſe touches allowed to remain viſible, and decided both of light and of dark; alſo how they characterized by their execution of the different parts; for, in a well executed work no touches are allowed to remain that are not neceſſary in ſome meaſure to determine the character of the object; the reſt are all blended or ſoftened together, and ſerve as a baſe to receive thoſe finiſhing touches (as they are called) which are the decided features of the ſtyle of the maſter, (ſee Style, in *Painting*,) the ſpring of energy and vigour in the work, and without which it would appear tame and inſipid.

A picture, wherein the colours and forms are blended all over, is ſure to appear either ſolid like a ſtone, or have the texture of dough, of ſomething ſoft and ſpiritleſs. On the contrary, where no ſoftening takes place, and every touch remains viſible, confuſion inevitably reigns, with the character of tinſel, and a fluttering want of ſolidity.

While the ſtudent is endeavouring to acquire facility of handling his pencil, or of execution, he muſt take care not to be led away by its faſcination, but to remember that it is only the means of preſenting to the world, in an agreeable ſhape, other more dignified, and more valuable qualities in art, which lie deeper than the ſurface; and without which this is worſe than an empty nothing. 'Tis the bane of many an ingenious youth who, happening to poſſeſs it early, and outſhining his companions in years, ſatisfies himſelf that he has made a large advance in his art, when in fact he has obtained only a means of doing ſomething, which more important part, his vanity leads him to forget to make the ſtudies requiſite to enable him to perform, *viz.* to acquaint himſelf thoroughly with the nature of bodies, and the happieſt and beſt modes of combining them in forms and colours: and as he advances in life he is mortified to find himſelf ſurpaſſed by thoſe he had regarded with contempt, but whoſe more ſteady and better directed minds have purſued attentively more valuable objects of ſtudy, and the more uſeful principles of their art, and now ſoar to a height which leaves his weaker talent far beneath.

It muſt, however, be remarked, that a good execution is a highly valuable quality in a picture, which being wrought with judgment, with ſpirit, and eaſe, acquires thereby an additional reliſh to the enjoyments its better properties diſpenſe, and raiſes the artiſt in our eſtimation.

Of all thoſe who have exhibited this talent with ſucceſs, Giacomo Robuſti, called Il Tintoretto, ſtands foremoſt for vigour, as has been noticed under the word Energy, in *Painting*. He has no competitor in the freedom, the boldneſs, and the finiſh of ſtyle in which his beſt works are executed.

Of this his picture of St. Mark deſcending from heaven to reſcue a Chriſtian ſlave condemned to torture among the Turks, originally painted for the Scudo di San Marco at Venice, but now among the ſpoils adorning the Louvre at Paris, is a moſt decided and aſtoniſhing proof. This picture is an immenſe work containing twenty figures or more, thoſe in front larger than life, yet it is wrought all over with the rapidity and eaſe generally characteriſtic of ſmall pictures, or a ſketch within the compaſs of the hand to perform at once; and at the ſame time it has all the effect of rotundity of finiſh the moſt laboured works poſſeſs. In the midſt of the fine pictures which ſurround it, it ſtands quite alone in its vigour of effect and ſplendour of valour; even a work of Rubens, who is extremely ſkilful in this as well as in all other branches of the art; even his, appeared comparatively clumſy in its execution, though one of his fineſt productions, the opening of the Temple of James, or, as it is uſually called, the Peace and War. Titian, from his ſenſe and truth in the St. Peter martyr, beſt withſtands the power of Tintoretto. The compariſon of theſe two works may be ſaid to be ſomewhat ſimilar to that of a man of wit with a man of ſenſe: the former ſhines for a moment by the brilliancy and gaiety of his genius, but when the latter is attentively heard, and his obſervations conſidered, his greater value becomes apparent.

Titian perhaps on the whole is the beſt model to follow for execution: he does not, like Tintoretto, leave his heads without a character in the heat of workmanſhip, though they are not always of the beſt; they are not wrought too minutely: the lights and darks are freely placed, his pencil is full and rich, and each part is made out to its full relievo, and his finiſhing touches are laid on with the niceſt diſcrimination of truth in direction of light and hue of colour; nothing can exceed the delicacy and ſkill his draperies are wrought with as to character; and though not ſo ſtrong as Tintoretto's, they have ſufficient force, and are far more juſtly diſpoſed and characterized. After Titian in imitating him are, Velaſquez and Vandyke for excellence in their execution. Of the former, a Spaniſh painter, there are but few works in this country, but what there are, fully juſtify the remark. The latter in his very fineſt works equals his great predeceſſor in this reſpect, many of whoſe pictures he carefully copied. His touch is exceedingly delicate, and his underſtanding of his ſubject enabled him to place it with the greateſt juſtneſs and propriety. There is rarely ſeen in his works a confuſion in effect or relievo, and his power in his earlier productions ſeems to have encreaſed with his canvas; the large picture at Wilton of the Pembroke family is wrought in a ſtyle ſo broad and maſterly, that it appears to have been as eaſily managed as any of his ſmaller pictures; and he knew how to give with the greateſt eaſe the juſt character of every object he attempted to repreſent. Gout and conſequent weakneſs effected a change in his execution ſo great, that his hand is hardly cognizable in ſome of his latter works by thoſe who have only ſeen his former ones. When he was in Italy, his manner was that of Titian, with ſomewhat of Tintoretto; from this bravura ſtyle, as it may be termed, he fell afterwards to one more tame and ſpiritleſs; ſoftened, and rounded up, with few of thoſe vigorous touches, and with leſs billiancy of effect. Inſtances of both theſe, and alſo intermediate degrees, are at the earl of Egremont's at Petworth. Of the firſt are whole length portraits of ſir Robert and lady Shirley, which he painted when he was very young at Venice; of the others, are portraits of ſeveral branches of the Pony family, who once poſſeſſed that noble manſion. Vandyck certainly ſurpaſſed his maſter Rubens in beauty of execution, but was more than equally ſurpaſſed by him in vigour and variety of imagination; yet the execution of Rubens was extremely powerful, but apt to become ſlovenly, and he is not, generally ſpeaking, a good model to be followed on that head.

For thoſe who are intent upon yielding the ſoft, the delicate, and gentle impreſſions produced by highly laboured works without minuteneſs, Correggio is the exemplar of the whole claſs of that ſtyle of painters. In one particular he, and our own ſir Joſhua, in ſome of their works, ſtand unrivalled in execution. Other painters have given a beautiful ſurface, which, at a proper diſtance, deceives the eye, and preſents the full appearance of fleſh: theſe two have, we may almoſt ſay, made fleſh itſelf; the cloſeſt inſpection merely confirms the deluſion, and the obſerver fancies he could indent his finger in the ſurface, and expect it to ſpring again like nature;

ſuch is the fullneſs of the texture of the colour wrought with the many varying hues of nature. Guido Rheni follows in this claſs of the pleaſing ſtyle. His pictures of the lighter kind are exceedingly grateful to the eye, from the intelligence and eaſe with which his pencil appears to have been conducted through all the various parts. Annibal Carracci, in a more bold manner, is alſo a maſter of great power in the execution part of the art; but he often appears to have laboured to expreſs his thoughts; his works, however, poſſeſs great beauties of this nature.

In works of a different and ſmaller claſs from thoſe produced by the maſters whoſe names we have mentioned, almoſt the whole of the Dutch and Flemiſh ſchools are wonderfully ſkilful in their execution, particularly Rembrandt, Teniers, Janſſen, Metzu, Netſcher, &c. and ſtill more minute Gerard Dow, and Meins. In landſcape, Cuyp, Berghem, Both, Ruyſdael, and Hobbima, are all well worthy of the utmoſt attention in this reſpect; and many others, too numerous to be mentioned here, both of theſe and the Italian ſchool, will greatly aſſiſt the ſtudent who attentively examines their productions to form his judgment, on thoſe points wherein lie the greateſt beauties of this neceſſary branch of the art of painting. But as a good execution conſiſts in a free and ready hand, marking with fullneſs of preciſion and truth the characters of the objects repreſented; nothing but an intimate knowledge of nature will ever enable him to apply his obſervations on works of art to any beneficial purpoſe in completing the productions of his own imagination.

EXECUTIONE *facienda*, in *Law*, a writ commanding execution of a judgment.

Executione *facienda in withernamium*, lies for taking the cattle of one who had formerly conveyed out of the county the cattle of another, ſo that the ſheriff cannot replevy them.

Executione *Judicii*, a writ directed to the judge of an inferior court, to do execution upon a judgment therein, or to return ſome reaſonable cauſe wherefore he delays the execution. F. N. B. 20.

If execution be not done on the firſt writ, an *alias* ſhall iſſue, and a *pluries*, with this clauſe, *vel cauſam nobis ſignifices quare*, &c. And if, upon this writ, execution be not done, or ſome reaſonable cauſe returned why it is delayed, the party ſhall have an attachment againſt him who ought to have done the execution, returnable in B. R. or C. B. New. Nat. Br. 43.

EXECUTIVE Power, *Supreme*, is by the conſtitution of theſe kingdoms lodged in a ſingle perſon, the king or queen for the time being. See Crown and King.

EXECUTOR, a perſon nominated by a teſtator, to take care to ſee his will and teſtament executed or performed, and his effects diſpoſed of according to the tenor of the will.

The teſtaments made in Latin, in the fourteenth century, call executors *proviſores teſtamentarii*.

All perſons are capable of being executors that are capable of making wills, and others beſides, as feme-coverts and infants, and infants unborn; (Weſt. Symb. p. 1. § 635.) but no infant can act as executor till he is ſeventeen years of age. This appointment of an executor, either by expreſs words, or by ſuch as ſtrongly imply the ſame, is eſſential to the making of a will; (Weſt. c. 1. Plowd. 281.) but if the teſtator names no executors, or names incapable perſons, or if the executors that are named refuſe to act, the ordinary muſt grant letters of adminiſtration. See Administrator.

A perſon appointed to be executor is not compellable to execute the will; he may refuſe the charge, before he has adminiſtered as executor, or performed ſuch acts, as paying debts due by the teſtator, or receiving debts due to him, or giving acquittances for the ſame; but if he meddles with the goods of the teſtator, as executor, his ſubſequent refuſal is void, and he ſhall be charged as executor. A perſon to whom a legacy is left may be compelled either to ſtand the executorſhip, or to reſign his legacy. The refuſal of executorſhip muſt be entered and recorded in court. If ſeveral executors are named in a will, and ſome of them refuſe, and others prove the will, they who refuſe may afterwards adminiſter and act; and they muſt be joined in all ſuits, where the co-executors are plaintiffs; but not where they are defendants, becauſe the plaintiff in the action is not bound by law to take notice of any beſides thoſe who have proved the will. Such joint-executors, though they are accounted in law but as one perſon, ſhall not be charged by the acts of their companions, any further than for effects *actually* come to their hands. (Moor. 620. Cro. Eliz. 318. 2 Leon. 209.) But if two or more executors join in a receipt (in writing) and one of them only actually receives the money, each is liable for the whole, as to creditors at law, but not as to legatees or next of kin. (1 Salk. 318.) If joint-executors, by agreement among themſelves, agree that each ſhall intermeddle with a certain part of the teſtator's eſtate, yet each ſhall be chargeable for the whole (to creditors) by agreeing to the other's receipts. Hard. 314.

The intereſt, veſted in the executor by the will of the deceaſed, may be continued and kept alive by the will of the ſame executor, ſo that the executor of A.'s executor is to all intents and purpoſes the executor and repreſentative of A. himſelf. (Stat. 25 Edw. III. ſt. 5. c. 5. 1 Leon. 275.) But the executor of A.'s adminiſtrator, or the adminiſtrator of A.'s executor, is not the repreſentative of A. For the power of an executor is founded upon the ſpecial confidence and actual appointment of the deceaſed; and ſuch executor is therefore allowed to tranſmit that power to another, in whom he has equal confidence; but the adminiſtrator of A. is merely the officer of the ordinary, preſcribed to him by act of parliament, in whom the deceaſed has repoſed no truſt at all; and therefore, on the death of that officer, it reſults back to the ordinary to appoint another.

As to the office or duty of an executor, it is to be obſerved that he may do many things before he proves the will, which an adminiſtrator cannot do; becauſe the former derives his power from the will, and not from the probate or appointment of the ordinary, as the latter does. (Comyns. 151. Wentw. ch. 3.) He may maintain actions of treſpaſs, replevin, or detinue; releaſe an action, aſſent to a legacy, be ſued, alien, or otherwiſe intermeddle with the goods of the teſtator: by adminiſtering, the executor is entitled to receive all debts due to the teſtator, and all payments made to him are good, though he ſhould die, and never prove the will; but he cannot maintain a ſuit or action of debt, or the like, before he has proved the will. The ordinary, &c. may cite the executor, either to prove the will, or refuſe the office; and he may ſequeſter the goods of the deceaſed, till the executor has proved it; and if he does not appear on the proceſs, the ordinary may excommunicate him. On the other hand, the ordinary is compellable by mandamus to proceed to probate, when the will is not controverted. The executor muſt bury the deceaſed in a manner ſuitable to the eſtate he leaves behind him; neceſſary funeral expences are allowed, previous to all other debts and charges; but if he be extravagant, he is chargeable with devaſtation, or waſte of the ſubſtance of the deceaſed, which ſhall be only prejudicial to himſelf, and not to the creditors or legatees of the deceaſed. (Salk. 196. Godolph. p. 2. c. 26. § 2.) He is then to make an inventory of all the goods and chattels, whether in poſſeſſion or action of the deceaſed, which he is to deliver in to the ordinary upon oath, if lawfully required. He is then to collect all the goods and chattels ſo inventoried; for which purpoſe the law confers on him ample powers, as the repreſentative of the deceaſed; (Co. Litt. 209.) and having the ſame property in his goods as the principal had when living, and the ſame remedies to recover them; and if there be two or more executors, a ſale or releaſe by one of them ſhall be good againſt all the reſt. (Dyer. 23.) The executor muſt in the next place pay the debts of the deceaſed, in the order of their priority. See Debt, and Debtee *Executor*.

Among debts of equal degree, the executor (and alſo the adminiſtrator) is allowed to pay himſelf firſt, by retaining in his hands ſo much as his debt amounts to. (10 Mod. 496.) If a creditor conſtitutes his debtor his executor, this is a releaſe or diſcharge of the debt, whether the executor acts or not, (Plowd. 184. Salk. 299.) provided there be aſſets ſufficient to pay the teſtator's debts.

If no ſuit has commenced againſt him, the executor may pay any one creditor in equal degree his whole debt, though he has nothing left for the reſt; for, without a ſuit commenced, the executor has no legal notice of the debt. After the debts, the executor is to pay the legacies, which he is to pay as far as his aſſets will extend; but he may not give himſelf the preference herein, as in the caſe of debts. In caſe of a deficiency of aſſets, all the *general* legacies muſt abate proportionably, in order to pay the debts; but a *ſpecific* legacy, as of a piece of plate, horſe, &c. is not to abate at all, unleſs there be not ſufficient without it. (2 Vern. 111.) If the legatees have been paid their legacies, and debts come in more than enough to exhauſt the reſiduum, they are afterwards bound to refund a rateable part. (Ibid. 205.) See Legacy, and Donation *Cauſa Mortis*.

When all the debts and legacies are diſcharged, the ſurplus or reſiduum muſt be paid to the reſiduary legatee, if any be appointed by the will; if there be none, it was formerly underſtood to belong to the executor; (Perkins, 525.) but it ſeems to be now the general opinion, that, if there be an expreſs legacy given to an executor, and no deviſe of the ſurplus, ſuch ſurplus ſhall not go to the executor; but be diſpoſed to the next of kin, according to the ſtatute of diſtributions; the executor ſtanding on the ſame footing as an adminiſtrator. (Prec. Chanc. 323. 1 P. Wms. 7. 544. 2 P. Wms. 338. 3 P. Wms. 43. 194. Stra. 559.) See Inteſtate.

Where no expreſs legacy is given to the executor, the ſurplus ſhall go to the executor, and not otherwiſe diſpoſed of by will. When there are ſeveral executors, and ſome of them are dead, the legatary muſt ſue the ſurviving executors, and not the executors or adminiſtrators of thoſe that are dead. And if all the executors are dead, he muſt ſue the executors or adminiſtrators of thoſe that died laſt, and not thoſe of the reſt.

By the French law, an executor ſhould be ſeiſed of all the moveables of the deceaſed during one year; at the end whereof he is to account for them. To the validity of a teſtament, it is not neceſſary there be an executor nominated therein.

Executor *de ſon tort*, or of his own wrong, is he who takes on him the office of an executor by intruſion, not being conſtituted thereto by the teſtator or deceaſed, nor authorized by the ordinary to adminiſter.

If an executor in his own wrong takes upon himſelf the office of an executor, without lawful authority, he is chargeable to the rightful executor, and to all the creditors of the teſtator, and likewiſe to the legatees, ſo far as the goods amounted to, which he wrongfully poſſeſſed; and ſuch an executor is made by any act of acquiſition, transferring, or poſſeſſing himſelf of any of the eſtate or goods of the deceaſed; but not by acts of neceſſity, piety, or charity. (2 Nelſon Abr. 793.) Such an executor cannot bring an action in right of the deceaſed; but actions may be brought againſt him; neither can he retain for his own debt or legacy. In caſe of his death, his executors or adminiſtrators are liable to the ſuit of the lawful executor, creditors, and legatees, by 30 Car. II. cap 7.

Executor, *Debtee*. See Debtee.

EXECUTORY, that which has, or carries with it a ſufficient authority for being executed.

Executory *contract*. See Contract.

Executory *deviſe of lands*, is ſuch a diſpoſition of them by will that thereby no eſtate veſts at the death of the deviſor, but only on ſome future contingency.

It differs from a *remainder* (which ſee) in three very material points; 1. That it needs not any particular eſtate to ſupport it. 2. That by it a fee-ſimple, or other leſs eſtate, may be limited after a fee-ſimple. 3. That by this means a remainder may be limited of a chattel intereſt, after a particular eſtate for life created in the ſame. The *firſt* caſe happens, when a man deviſes a future eſtate to ariſe upon a contingency; and, till that contingency happens, does not diſpoſe of the fee ſimple, but leaves it to deſcend to his heir at law. As if one deviſes land to a feme-ſole and her heirs upon her day of marriage; here is in effect a contingent remainder without any particular eſtate to ſupport it; a freehold commencing *in futuro*. This limitation, though it would be void in a deed, yet is good in a will, by way of executory deviſe. (1 Sid. 153.) For, ſince by a deviſe a freehold may paſs without corporal tradition or livery of ſeiſin, it may therefore commence *in futuro*; becauſe the principal reaſon why it cannot commence *in futuro* in other caſes is the neceſſity of actual ſeiſin, which always operates *in præſenti*. And ſince it may thus commence *in futuro*, there is no need of a particular eſtate to ſupport it; the only uſe of which is to make the remainder, by its unity with the particular eſtate, a preſent intereſt. And hence it follows, that ſuch an executory deviſe, not being a preſent intereſt, cannot be barred by a recovery, ſuffered before it commences. (Cro. Jac. 593.) The *ſecond* caſe happens where a deviſor deviſes his whole eſtate in fee, but limits a remainder thereon to commence on a future contingency. As if a man deviſes land to A. and his heirs; but if he die before the age of 21, then to B. and his heirs; this remainder, though void in a deed, is good by way of executory deviſe. (2 Mod. 289.) But in both theſe ſpecies of executory deviſes, the contingencies ought to be ſuch as may happen within a reaſonable time; as within one or more life or lives in being, or within a moderate term of years; for courts of juſtice will not indulge even wills, ſo as to create a perpetuity, which the law abhors. (12 Mod. 287. 1 Vern. 164.) *Thirdly*, by executory deviſe a term of years may be given to one man for his life, and afterwards limited over in remainder to another, which could not be done by deed; for by law the firſt grant of it, to a man for life, was a total diſpoſition of the whole term; a life eſtate being eſteemed of a higher and larger nature than any term of years. (8 Rep. 95.) On this ſubject, ſee Blackſt. Comm. vol. ii. p. 176, 8vo.

Executory *eſtate*. See Estate.

Executory *fine*. See Fine.

EXEDENS Herpes. See Herpes.

EXEDRÆ, Εξεδραι, among the *Ancients*, were places wherein the philoſophers, ſophiſts, rhetors, &c. uſed to hold their conferences and diſputes.

M. Perrault is of opinion, the exedræ were a ſort of little academies, where the men of learning met together. See Academy.

Budæus rather thinks, that what the ancients called exedræ, might anſwer to what we call chapters in the cloiſters of monks, or collegiate churches.

EXEGESIS, Εξηγησις, a term ſometimes uſed by the learned, to ſignify *explication*.

Several interpreters of the Bible are of opinion, that in the paſſages of Scripture, where we meet with Abba Pater, two words, the firſt Syriac, and the ſecond Greek or Latin, but both ſignifying the ſame thing; the ſecond is only an exegeſis, or explanation of the firſt.

Exegesis is alſo uſed for an entire diſcourſe by way of explication or comment on any thing.

Exegesis *numeroſa*, or *linealis*, ſignifies the numeral, or lineal ſolution, or extraction of roots, out of adfected equations, firſt invented by Vieta. Ozanam calls it *la rhetique*. See Extraction *of roots*.

EXEGETES, formed of εξηγεομαι, *I explain*, among the Athenians, perſons learned in the laws, whom the judges uſed to conſult in capital cauſes.

EXEGETICA, in *Algebra*, the art of finding, either in numbers or lines, the roots of the equation of a problem, according as the problem is either numerical or geometrical. See Root and Equation.

EXELCOSIS, from ελκος, *an ulcer*, in *Surgery*, an incipient ulceration, or an excoriation, which is juſt beginning to ſuppurate.

EXEMPLAR, a model or original to be imitated or copied.

Exemplar alſo denotes the idea or image conceived or formed in the mind of the artiſt, whereby he conducts his work. Such is the idea of Cæſar, which a painter has in his mind when he goes to make a picture of Cæſar. The exemplar is ordinarily numbered among the cauſes. See Cause.

EXEMPLIFICATION *of Letters Patent*, denotes an exemplar, or copy of letters patent, made from the inrolment thereof, and ſealed with the great ſeal of England.

Such exemplifications are as effectual to be ſhewed, or pleaded, as the letters patent themſelves.

EXEMPLIFICATIONE, in *Law*, is a writ granted for exemplification of an original record. Reg. Orig. 290.

EXEMPTION, a privilege, or diſpenſation, whereby a perſon is excepted out of ſome general rule.

Exemption is particularly applied to churches, chapels, and monaſteries, which have a privilege given them by the popes, or princes, whereby they are exempted from the juriſdiction of the biſhop or ordinary.

The council of Conſtance revoked all exemptions, to reſtore to the general law, weakened and diminiſhed by a relaxation of ſeveral ages, its ancient force and vigour, and make it every where obtain in all its latitude.

The council of Trent prohibited, and declared them null for the future; confirming only ſuch as were well founded on legal conceſſions from the holy ſee.

Exemption, in *Law*, denotes a privilege to be free from ſervice or appearance; thus, knights, clergymen, &c. are exempted from appearing at the county courts by ſtatute, and peers from ſerving on inqueſts. (6 Rep. 23.) Perſons ſeventy years of age, apothecaries, &c. are alſo exempted by law from ſerving on juries, and juſtices of peace, attornies, &c. from pariſh offices. 2 Inſt. 247.

EXERCISE, a repetition of any operation, for the ſtrengthening or retaining of a habit.

Exercise, or bodily motion, conſtitutes, in the language of the older phyſicians, one of the ſix *non-naturals*, and has been juſtly conſidered, from the earlieſt times, as an important meaſure in the preſervation of health, as well as in the cure of ſeveral diſeaſes.

The value of corporeal exercifes in the eſtimation of the ancient phyſicians, from Hippocrates downwards, is manifeſt from their writings, in which the various kinds of exerciſe, as well as the degrees and times in which they are uſeful, are particularly diſcuſſed. Eſculapius himſelf is ſaid by Galen to have recommended riding on horſeback, and other exerciſes, as the means of benefiting invalids. But Herodicus, a Thracian, ſeems to have been the firſt who paid ſerious attention to exerciſe, as a remedy for diſeaſes. He was maſter of one of the academies, called *Gymnaſia*, in which the military and athletic exerciſes were taught; and having remarked that his pupils uſually enjoyed high health, he turned his attention to the regulation of the gymnaſtic exerciſes, with a view to attain or preſerve good health; thus adding the *medical gymnaſtic* art, to the two others juſt mentioned. (See Gymnastic, and Herodicus.) This maſter of the gymnaſium, however, went to work empirically, and is accuſed by Hippocrates of doing conſiderable miſchief, in attempting to cure febrile diſeaſes by his exerciſes. (De Morb. Epidem. lib. vi.) Hippocrates and his commentator, Galen, have left many obſervations relative to the different exerciſes, and their particular effects in the alleviation of particular diſeaſes. Friction, eſpecially by means of the *ſtrigil*, or fleſh bruſh, is much inculcated; on which ſubject Galen has compoſed his ſecond book, "De Sanitate Tuenda." The various modes of wreſtling, the exerciſes of the *corycus*, or hanging ball, &c. are commented on by Hippocrates in lib. ii. De Diæta: and Galen wrote a little treatiſe *de parva pila*, (the little ball,) which he recommends as an exerciſe that influences both the body and the mind at the ſame time. In his diſcourſe to Thraſibulus he diſcuſſes the queſtion, whether the preſervation of the health properly belongs to medicine, or to the gymnaſtic art: he inveighs againſt the athletic and other violent practices of the gymnaſium, but approves of the more moderate exerciſes, which he conſiders as ſubſervient to the purpoſes, and conſequently a part of the art of the phyſician. Antyllus, and other Greek writers, have treated of the various exerciſes in the ſame light, as is evinced by the collections of Oribaſius. (See Collect. Med. lib. vi.) The Romans even exceeded the Greeks in their attention to the medical gymnaſtics. Aſclepiades, in the time of Pompey, as Pliny informs us, conſidered the different modes of exerciſe, *viz.* friction, walking, and geſtation, as the chief auxiliaries of the phyſician, eſpecially when combined with the proper regulation of diet; and by the employment of theſe exerciſes, the inſtitution of baths, the invention of hanging beds, *lecti penſiles*, and other means of making phyſic agreeable, he is ſaid to have acquired the general applauſe of all mankind: "univerſum prope humanum genus circumegit in, &c." (Plin. Nat. Hiſt. lib. xxvi. cap. 3.) Many eminent examples of the benefits of exerciſe among the Romans are on record. Suetonius ſtates that Germanicus was cured of a ſort of atrophy of the lower extremities, (crurum gracilitas) by riding. And Cicero himſelf, when reduced to a ſtate of infirmity, which rendered it neceſſary for him to deſiſt from pleading, recovered his health by travelling, and by exceſſive diligence in the uſe of friction. (Plutarch.) Friction was an exerciſe, indeed, reduced to a regular ſyſtem among the ordinary habits of the Romans, and was preſcribed to a great extent by their phyſicians. See Friction.

That exerciſe, eſpecially in the open air, is highly beneficial to the conſtitution, is a truth which univerſal experience has eſtabliſhed. It is ſcarcely neceſſary, therefore, to appeal to the arguments of phyſiology to corroborate the propoſition. It may be ſufficient to ſtate, that the immediate reſult of bodily exertion is an acceleration of the circulation of the blood; a quicker and ſtronger contraction of the heart, by which the blood is puſhed more effectually to every part of the ſyſtem, and eſpecially through the ſmall and extreme branches of the veſſels. Hence a glow is produced on the ſurface, and the complexion aſſumes a redder hue, from the diſtention of the capillary veſſels with blood; and the exhalent arteries begin to pour out the thinner portions of the fluids in perſpiration. In the ſame manner, the extreme arteries of all the other parts of the body are diſtended, and excited to greater action; whence all the organs of ſecretion, which are principally made up of convolutions of the extreme arteries, are neceſſarily ſtimulated to an active performance of their ſeveral functions. The veſſels of the ſtomach pour out the gaſtric liquors more abundantly, and the work of digeſtion is more perfectly and actively completed; the appetite for a new ſupply of aliment quickly returns, and the ſtomach is prepared for repeating the digeſtive proceſs, by the increaſed ſupply of the digeſtive liquor. The liver and the pancreas, in like manner, elaborate their reſpective fluids, the bile and pancreatic juice, more copiouſly, and thus contribute an increaſed aid to the operations of the alimentary canal. The lungs, in the mean time, being called upon for an augmented ſupply of the vivifying principle derived from the oxygen of the atmoſphere, by the increaſed circulation of the blood through them, reſpiration is increaſed in proportion to the quantity of venous blood which they receive. Thus, notwithſtanding the greater rapidity with which the blood is carried to the ſecreting organs, it is rendered adequate to the ſecretion of the healthy fluids peculiar to each, by the increaſed operation of the lungs; as well as to the ſupport of the greater muſcular action, in which the exerciſe conſiſts.

It muſt be obvious, then, that this general activity of the whole ſyſtem, this free circulation through the moſt minute ramifications of the veſſels, and through the glands and organs which they compoſe, and this prompt ſeparation of the excrementitious and other parts of the blood, by the ſecretions, cannot but contribute to the general health of the body. It is not leſs obvious that it contributes to the evolution and growth of the different parts of the body; whether we conſider the great influx of the blood, from which all growth is derived; or obſerve the fact, that thoſe muſcles and limbs, which are moſt actively exerciſed, invariably acquire ſuperior bulk, as well as ſuperior ſtrength. The muſcles of the arms in blackſmiths, and thoſe of the loins in porters, and all others employed in raiſing or carrying great weights, invariably acquire a diſproportionate ſize; and, on the contrary, thoſe muſcles which are little employed are apt to ſhrink, and to be comparatively enfeebled, as in the legs of tailors. The effect of exerciſe in giving ſtrength and rigidity of fibre to the muſcular or fleſhy part of animals is well known, and daily exemplified in the difference of texture in the wings and legs of birds which we uſe as food. In the common fowls, which ſeldom uſe the wing, and conſtantly employ the legs in walking, the hardneſs of the fleſh of the latter, and tenderneſs of that of the former, are notorious. From this influence of exerciſe in contributing to the growth and ſtrength of the animal body, we may obviouſly trace the final cauſe of that inſtinctive diſpoſition to activity and motion, which the young of all animals poſſeſs.

Regular exerciſe, not too violent in degree, nor continued too long, ſo as to induce exceſſive fatigue, is therefore to be conſidered as the moſt important preventive of diſeaſes. It is not eaſy to lay down rules by which it ſhould be regulated; ſince the conſtitution, age, ſtrength and habits muſt modify its effects in different individuals. A ſudden tranſition from a ſtate of reſt to violent exertion is injurious to the invalid, eſpecially after a full meal, or if continued until a profuſe perſpiration, or great laſſitude takes place; for this over-exertion neceſſarily leads to a languor and imperfect performance of all the vital actions, every organ partaking of the general fatigue. The various kinds of exerciſe may be conſidered under two claſſes, the active and the paſſive; the former being the reſult of our own muſcular activity, ſuch as walking, dancing, running, ſwimming, fencing, the military exerciſe, and different athletic games; the latter the reſult of communicated motion, as riding in a carriage, ſailing, ſwinging, friction, &c.; riding on horſeback, or driving a carriage, partakes in ſome meaſure of both the active and paſſive exerciſes.

Walking, which ſeems to be the moſt natural exerciſe, is capable of producing all the effects above detailed, if adapted in degree and duration to the various circumſtances. Hence the moſt obſtinate caſes of hypochondriacal diſorders, of indigeſtion, and other ſtomach complaints, have been frequently removed by perſeverance in walking, eſpecially in the open air of the country. But when the exerciſe of walking is adopted with a view to baniſh the complaints juſt mentioned, which a ſedentary life is apt to induce, it is moſt effectual when regularly and ſtrenuouſly purſued. That degree of walking, which, when reſorted to occaſionally, or with conſiderable intermiſſions, produces great fatigue and languor, and therefore is rather prejudicial than advantageous, would, if daily continued, ſoon ceaſe to fatigue, and would then contribute greatly to reſtore the healthy ſtate of the functions. It muſt be recollected that the animal vigour is conſumed, or, to uſe the language of Brown, the excitability is exhauſted, by the mental functions as well as by muſcular exertion; therefore, to carry with us, in our walks in ſearch of health, the brooding anxieties and cares of our profeſſions,—to attempt to combine ſtudy with ſuch exerciſe by reading, or by ſerious reaſoning in converſation, is to thwart the good effects of the plan. We may obſerve that, ſo incompatible is deep thought with muſcular exertion, that moſt people ſtop in the midſt of their activity, when their arguments require great reflection. Serenity of mind, and a relaxation from the ſerious occupations of life, are therefore neceſſary, when walking is reſorted to as a remedy.

Of the more violent ſpecies of active exerciſe, which can only be reſorted to as a preſervative from diſeaſe, by thoſe who are in a ſtate of good health, it is unneceſſary to ſpeak.

The modes of exerciſe which are particularly uſeful in the cure of diſeaſes, or in the reſtoration of the health of convaleſcents, are the different ſpecies of geſtation, eſpecially riding in carriages, or on horſeback, and ſailing.

The motion of a ſhip produces the moſt gentle exerciſe, and is therefore adapted even to the relief of very infirm conditions of the body, and it has been employed from early times in the cure of conſumption. The Romans, in the time of Pliny, uſed to ſend their conſumptive patients to Egypt; not, as that author takes care to inform us, on account of any peculiarity of that country, but in conſequence of the length of the voyage. Annæus Gallio, who had been conſul, was cured of a conſumption by ſuch a voyage. (Nat. Hiſt. lib. xxxi. cap. 6.) Celſus ſeems to have conſidered ſailing, when reſorted to early, as the principal remedy for conſumption: "opus eſt, ſi vires patiuntur, longa navigatione," he ſays; and where the ſtrength is not equal to it, he recommends ſhort voyages, or the uſe of a litter, or other means of gentle geſtation. (De Medicina, lib. iii. cap. 22.) The advantages of a ſea voyage, eſpecially to a warmer climate, are well known to modern phyſicians; and inſtances of the ſucceſs of ſuch a voyage to Madeira, Liſbon, &c. when undertaken in the incipient ſtage of conſumption, as Celſus recommends it, are very numerous. This, however, like all other remedies for conſumption, is too often reſorted to when the diſeaſe has already advanced too far to admit of any effectual relief. See CONSUMPTION.

The exerciſe of geſtation by means of a carriage, and the more active exerciſe of riding on horſeback, being more eaſily obtained, are of more importance in our conſideration of the ſubject. Horſeback exerciſe was not much adopted by the ancients, with a view to the cure of diſeaſes; partly becauſe that valuable animal was leſs uſed by the Greeks and Romans, and partly becauſe their mode of riding, without ſtirrups, was incompatible with the weakneſs of invalids. (See Fuller, Medicina Gymnaſtica, p. 231.) Hence we may underſtand the obſervation of Antyllus, that "riding is of little uſe to thoſe who are ſickly, becauſe a ſlow pace is productive only of laſſitude, eſpecially in the loins;" he admits, however, that "a quick pace of the horſe, although it occaſions a troubleſome ſhaking of the whole body, is nevertheleſs ſomewhat beneficial, and ſtrengthens the ſyſtem, eſpecially the ſtomach and the organs of ſenſe, more than all other exerciſes." (Oribaſius, loc. cit. lib. vi. cap. 24. de Equitatione.) The great advantages of riding in the prevention and cure of many diſeaſes are inſiſted upon in the ſtrongeſt terms by Sydenham, who, indeed, appears, in ſeveral parts of his writings, to have conſidered it as a remedy of ineſtimable value, provided it be perſevered in with conſtancy, in the manner which we have inculcated in reſpect to *walking*. Speaking of the mode of cure in chronic diſeaſes, that ſagacious phyſician obſerves, "nothing, among all the expedients which have hitherto come to my knowledge, ſo effectually ſupports the ſpirits and ſtrength, as long and conſtant riding on horſeback." (Diſſ. Epiſtolaris.) Again in his Treatiſe on the Gout, and particularly reſpecting the prevention of the paroxyſms by exerciſe, he ſays, "riding on horſeback is far preferable to all other exerciſes for this purpoſe; in truth I have frequently conſidered, that if any perſon were acquainted with a medicine, which he choſe to keep ſecret, of equal efficacy in this, and in the greater number of chronic diſeaſes, with a conſtant and perſevering exerciſe on horſeback, he would ſpeedily accumulate the moſt ample wealth." And to expreſs his full conviction of the value of this exerciſe in conſumptive complaints, he uſes theſe ſtrong terms: "in ſhort, however fatal conſumption is deemed to be, and actually is, ſince it deſtroys two thirds of thoſe who die of chronic diſeaſes, yet I ſolemnly affirm, that neither is mercury a more effectual remedy for the lues venerea, nor Peruvian bark for agues, than is the exerciſe juſt commended for conſumption, provided that the patient be always careful to ſleep in dry linen, and that his journey be ſufficiently long." The truth of this great encomium is indeed queſtioned by modern practitioners in general, however weighty the authority of Sydenham may be. But there are many caſes on record, which ſeem to juſtify this obſervation. Witneſs the caſe of the late Dr. Currie, of Liverpool, as related by himſelf, in the Zoonomia of Darwin. (Vol. ii. claſs ii. Ord. i. 6.) In this caſe, the patient had an hereditary prediſpoſition to conſumption, and was reſtored by travelling from a ſtate of debility, in which the erect poſture could ſcarcely be borne without fainting, to good health; having begun with the exerciſe of a carriage, and afterwards ridden on horſeback, as his ſtrength augmented. Sydenham has related ſeveral examples of the value of this exerciſe, and others may be found detailed by Fuller, &c. We cannot therefore doubt, that in many inſtances, in which it has ſeemed to be deſtitute of the efficacy aſcribed to it by Sydenham, the failure muſt be attributed to the imperfect or too late uſe of the remedy. "I muſt here repeat," ſays Fuller, quaintly, "that when I ſpeak of riding, I underſtand the *habit of riding*, the want of which diſtinction has made it ineffectual to many a man. He that in this diſtemper (conſumption) above all others rides for his health, muſt be like a Tartar, in a manner always on horſeback; and then from a weak condition he may come to the ſtrength of a Tartar." (Medicin. Gymnaſt. p. 106.) We have dilated upon this topic, from a conviction that many chronic diſeaſes, which are included under the epithets of bilious and nervous, as well as many morbid conditions of the viſcera, for which drugs, and even the waters of Briſtol, Bath, and Cheltenham, are ineffectually ſwallowed, might be removed by a ſteady and unremitting exerciſe, in a carriage, or ſtill more certainly on horſeback.

It is unneceſſary to enter into a particular enumeration and diſcuſſion of every poſſible form of exerciſe, the principle being the ſame with reſpect to all. A late intelligent writer has laid down ſome uſeful practical precepts on theſe topics, mixed with a good deal of trifling obſervation, and abſurd hypotheſis. (See Willich's Lectures on Diet and Regimen, chap. 7.) The following remarks on the injuries occaſioned by want of exerciſe are from that popular writer.

"We are now to conſider the conſequences ariſing from *want of exerciſe*. This, indeed, is ſtill more debilitating than too violent motion. The ſolid parts of the human frame are relaxed by it; the circulation of the fluids is retarded; they gradually ſtagnate in the ſmaller capillary veſſels; the ſecretions are diminiſhed; and abundance of moiſture or fat is generated, which renders the body, as well as the mind, more indolent and lethargic, relaxation of the muſcles, obſtructions of the inteſtines, hemorrhoids, apoplectic fits, various ſpecies of dropſy, and at length a premature death, are the ſad conſequences. Men of letters are the moſt unhealthy of all human beings, becauſe their bodies have ſcarcely any other exerciſe but the imperceptible motion of the arms. Want of appetite, flatulency, anxiety, at one time obſtructions, at another diarrhœa, and the moſt diverſified nervous ſymptoms are their attendants. Sleep is beyond their reach; a thouſand tormenting inconveniences, hypocondriaſis, and at length a complete ſtate of melancholy, is too frequently their lot. Temperance alone will not remedy all theſe evils; for, ſince we cannot remain vigorous and healthy for two days together, with the ſame maſs of blood, a new acceſs of the neweſt and moſt ſubtle parts of our fluids muſt daily ſupport the nervous ſyſtem, in order to preſerve its regular functions. If this be not continually reſtored, weakneſs and relaxation of body and mind are the inevitable conſequences; with this difference only, that in a ſtate of debility from too much bodily exerciſe, the thick and coarſe particles of the fluids are carried into circulation with the others, and the next meal or the firſt ſleep after it, ſoon ſupplies the deficiency in mental labour; on the contrary, digeſtion is interrupted, the crude and viſcid parts of food remain unaſſimilated, and the body is prevented from receiving proper nouriſhment. In like manner ſedentary mechanics and artificers are affected, particularly ſhoe makers, tailors, and weavers. They experience maladies ſimilar to thoſe to which men of letters are ſubject; and it has been frequently obſerved, that they are very liable to diſeaſes of the mind, and eſpecially to religious fanaticiſm."

Exercise, *Field*, in *Military Affairs*, relates to the evolutions performed by companies, regiments, or greater bodies of troops, when learning, or practiſing, thoſe movements neceſſary to be correctly underſtood by perſons of all ranks in the military profeſſion. See Evolutions and Tactics.

Exercise, *Gun*, relates to the ſeveral arrangements, and motions, made for ſerving either heavy or light artillery, under every circumſtance common to military operations. See Gun-*Exerciſe*.

Exercise, *Manual*, teaches the ſeveral motions of the firelock, whereby all act as it were in uniſon, and perform their duties when drawn up for diſplay, or for ſervice, in an uniform and appropriate manner. See Manual-*Exerciſe*.

Exercise, *Sword*, refers to the ſeveral poſitions of the ſword, adapted either for attack, defence, or compliment. See Sword-*Exerciſe*.

Exercise, in a *Naval Senſe*, is the preparatory practice of managing the artillery and ſmall arms, in order to make the ſhips' crew perfectly ſkilled therein, ſo as to direct its execution ſucceſsfully in time of battle. The words of command introduced, during the late war, for the exerciſe of the great guns, are the following: "Silence: caſt looſe your guns; level your guns; take out your tompions; run out your guns; prime; point your guns; fire; ſpunge your guns; load with cartridge; ſhot your guns; put in your tompions; houſe your guns; and ſecure your guns. Falconer's Marine Dict. art. *Exerciſe*.

Exerciſe may alſo denote the execution of the movements, which the different orders and diſpoſitions of fleets occaſionally require, and which the ſeveral ſhips are required to perform, by means of ſignals.

Exercises, in the plural, are particularly underſtood of what is taught young gentlemen in the academies, or riding-ſchools, &c. As riding the great horſe, dancing, fencing, vaulting, drawing fortifications, &c.

EXERGASIA, Εξεργασια, *Expoſition*, in *Rhetoric*, a figure conſiſting of ſeveral equivalent expreſſions, or ſuch as are nearly ſo, in order to repreſent the ſame thing in a ſtronger manner. The warmth and vehemence of the ſpeaker often urge him to recur to this figure, when he is affected with his ſubject, and there are no words, no expreſſions, ſufficiently forcible to expreſs his ſentiments; and he therefore repeats one after another, as his fancy ſuggeſts them. This flow of expreſſion, under the conduct of a good judgment, is often attended with advantage; as it warms the hearers, and impreſſes their minds, excites their paſſions, and enables them to ſee things in a ſtronger light.

EXERGUM, Exergue, or *Exerge*, often denominated by Evelyn *exurge*, among *Medaliſts*, is the bottom of a coin, commonly ſeparated from the field by a line, upon which the figures of the reverſe ſtand. It is ſo called from being εξ εργου, *out of the* work of the medal. When the letters or words of a medal run round the margin, are on either ſide of the figure, or upon the exergue, they are denominated a *legend*; but when they occupy the field, they are called an inſcription. See Legend and Inscription.

EXETER, in *Geography*, a city in Devonſhire, England is of great antiquity, and, as Riſdon emphatically ſtyles it "may be called the emporium and principal ornament of the weſt." Its Roman name, as it appears in Ptolemy, is *Iſca*; and it is conjectured that the ſecond legion of Auguſta was ſtationed here for ſome time: this was commanded by Veſpaſian, who was the conqueror of Britannia Prima, in which province this place was included. In the Itinerary of Antoninus, Exeter is called Iſca-Danmoniorum, and is the moſt weſterly ſtation he has noticed: though, from the Iters of Ptolemy and Richard; from the remains of Roman roads over, and around Haldon; and from the veſtiges of ancient ways through Drew-Teignton to Oakhampton, and perhaps of a road hence over Dartmoor, by Hollow-ſtreet in the pariſh of Chagford; it is apparent that various principal roads ran weſtward from this city; and, therefore, it is probable that the Romans had other ſtations weſt of this. How long Exeter retained the name of Iſca-Danmoniorum is uncertain; though it ſeems probable that it fell into diſuſe very ſoon after the Romans quitted the iſland, about which time it appears to have been re-occupied by the Britons who had preſerved their independence by retiring to the wilds of Cornwall. They did not, however, continue in the poſſeſſion of it many years; for Cerdic, the founder of the kingdom of Weſſex, having greatly extended his territories, either by conqueſt or intrigue, included the moſt conſiderable portion of Devonſhire within his dominions: and at length Exeter became ſubjugated to the power of the Saxons. Under their government its name was changed to Evan-Ceſtre, Ex-Ceſtre, &c., and thence, through various ſimilar appellations, ſoftened to Exeter.

This city has been ſeveral times beſieged; but the greateſt calamities it experienced were inflicted by the Danes, who, in the reign of Alfred, in violation of a ſolemn treaty, ſurpriſed and routed the king's horſemen, and mounting their ſteeds, rode to Exeter, and remained there for the winter. Alfred collected all his forces and inveſted the city by land, while his fleet blocked up the harbour: the Danes capitulated, and agreed to evacuate all the territories of the Weſt Saxons. Between the period of the death of Alfred and the reign of Athelſtan, the Corniſh Britons had recovered poſſeſſion of Exeter; but Athelſtan having defeated and driven them to the weſt of the Tamar, they were never afterwards able to oppoſe the Saxon arms. To ſecure his conqueſts he ſurrounded Exeter with a wall of hewn ſtones defended by towers: and under his auſpices, ſays Malmſbury, "it became ſuch a place of trade, that it abounded with opulence." He adds that many other remarkable works of Athelſtan were to be ſeen in the city and its neighbourhood. In the year 1003 Exeter was the firſt ſacrifice to the fury of Swein king of Denmark, when he came to revenge the inhuman maſſacre of his countrymen: being delivered up by the treachery of its governor, after a ſiege of two months, many of the inhabitants were put to the ſword, and moſt of the buildings deſtroyed by fire. Before it was well recovered from this calamity, it was again beſieged and taken by William the Conqueror. In the reign of Stephen, this city was alternately garriſoned by the forces of the king and the empreſs. It again became the ſcene of hoſtility during the conteſt between Henry VI. and Edward IV. In the reign of Henry VII. it was cloſely, though ineffectually, beſieged by three thouſand men under Perkin Warbeck. The laſt ſiege Exeter experienced was in Edward VI.'s reign, when religious innovations occaſioned an alarming inſurrection in the weſt of England: the inhabitants, though reduced nearly to famine, ſo bravely defended the city for thirty-five days, that the inſurgents abandoned their deſign.

The ground incloſed within the walls of the city is nearly in the form of a parallelogram, of four furlongs in length, and three in breadth: this ſpace is interſected by the four principal ſtreets which meet near the centre, and diverging at right angles, connect the city with the ſuburbs. The whole extent occupied by buildings is about one mile and three quarters in length, and one mile in breadth. In the year 1769 the ſurrounding walls were entire; but many parts have been ſince deſtroyed. Stukeley ſpeaks of them as being, in his time, in pretty good repair, and having many turrets and towers, various parts of which are ſtill remaining. Leland, ſpeaking of this city, obſerves, that it is "a good mile and more in cumpace, and is right ſtrongly waullid and maintainid. Ther be diverſe fair towers in the toune waul bytwixt the ſouth and the weſt gate. Ther be four gates in the toune, by the names of eſt, weſt, north, and ſouth. The eſt and the weſt gates be now the faireſt, and of one faſcion of building: the ſouth gate hath beene the ſtrongeſt." In the year 1769 the north gate was taken down, to make a more convenient entrance into the city; and in 1784 the eaſt gate was removed for the ſame purpoſe. The ſouth gate, the interior arch of which Dr. Stukeley remarks to be of Roman workmanſhip, is intended to experience the ſame fate.

The ſituation of Exeter is commanding and pleaſant: it ſtands on the acclivity of an eminence on the eaſtern banks of the river Exe, which flows in a ſemi-circular direction round the ſouth-weſt ſide of the city. "What adds to its wholeſomeneſs and cleanlineſs," ſays Stukeley, "is, that the ground is higher on a ridge along the middle of its length declining on both ſides. Further, on the ſouth-weſt and north-weſt ſides it is precipitous; ſo that with the river, the walls, the declivity of ground, and ditch without ſide, 'twas a place of very great ſtrength, and well choſe for a frontier." In the higheſt part of the city, on the north ſide, ſtand the remains of Rougemont caſtle, which was formerly the ſeat of the Weſt Saxon kings, and afterwards of the dukes of Exeter. This building has little to recommend it but its antiquity and pleaſant ſituation. The ruins of the exterior walls are nearly all that remain; theſe incloſe a conſiderable ſpace, of a pentagonal form, and were defended by four towers; two on the weſt, and two on the eaſt ſide. The ramparts of the caſtle command a moſt delightful view over the adjacent country. When the caſtle was erected is unknown; though Grafton's tale, that it was built by Julius Cæſar, is unqueſtionably falſe. William the Conqueror either rebuilt, or much repaired, the whole edifice, and beſtowed it on Baldwin de Briono, huſband of Albreda his niece, whoſe deſcendants, by the female line, enjoyed it, together with the office of ſheriff of Devon, which ſeems to have been annexed to it, till the fourteenth year of Henry III.'s reign, when that prince, reſuming into his own hands ſundry caſtles and forts in this realm, diſpoſſeſſed Robert de Courtney, in whoſe family it had been for three deſcents. In the civil war of the ſeventeenth century the caſtle was completely ruined, when the city withſtood a blockade of two months againſt Fairfax, one of whoſe forts, Mr. Gough ſays, ſtill remains in a field to the north. Within the area incloſed by the walls, a ſmall chapel was erected by lady Elizabeth de Fortibus, counteſs of Devon, who endowed it with lands, called the prebends of Hays and Catton, for the payment of certain weekly ſervices therein to be performed. A ſeſſions-houſe, of Portland-ſtone, has been recently built within the area on the north-weſt ſide.

Within the walls of the city are fifteen pariſh churches, and in the ſuburbs four; but moſt of them being ſmall, they preſent nothing worthy of particular deſcription.

The cathedral is a large intereſting edifice, and, according to Hooker and ſome other writers, was five hundred years in building; it conſiſts of a nave with two aiſles, a choir with aiſles, a north and ſouth tranſept, which are terminated by lofty towers. On the ſouth ſide was a large cloiſter, which is moſtly deſtroyed. To the eaſt of this is the biſhop's palace, which, with its gardens, are incloſed within a lofty wall. For a particular hiſtory and deſcription with ſeveral architectural points, ſee a large folio work publiſhed by the Society of Antiquaries.

The epiſcopal ſee of Devon was ſeated at Crediton previous to its eſtabliſhment at Exeter; but Leofric, who was biſhop of that ſee, and lord chancellor of England, prevailed on Edward the Confeſſor to remove it to the latter town in the year 1049. That monarch, in perſon, with Eadyga, his queen, attended the inſtallation, and placed the biſhop in his new ſee; which at the ſame time he endowed with the lands and emoluments appertaining to that of Crediton. The ſee being thus eſtabliſhed, it appears probable that a ſuitable cathedral was ſoon afterwards erected: but whether it was conſtructed by the enlargement and alteration of ſome exiſting edifice, or whether a ſeparate and entire building was now raiſed, is uncertain. "It ſeems not unlikely," obſerves ſir Henry Englefield, "that the firſt cathedral was not more than about ſixty feet in length, and occupied the ſite of the preſent chapel of St. Mary." That the chapel, in its preſent ſtate, was not the Saxon church, is ſatisfactorily proved by an examination of its architecture. No particular alteration appears to have been made in the cathedral before the time of William Warlewaſt, the third biſhop, who was a Norman, and had been chaplain to the Conqueror, and his two ſons, William and Henry; the latter of whom inducted him to this ſee in 1107. This prelate was a liberal benefactor to his cathedral; and it appears that he conſiderably enlarged it, and laid the foundation of the preſent choir: to him the towers yet remaining are probably to be aſcribed; they are perfectly ſimilar in ſtyle to the buildings of Gundulphus his cotemporary, and bear much more reſemblance to the magnificence of the Norman architects, than to the ſimplicity of the Engliſh Saxons.

Exeter has been from time immemorial, and ſtill is, inveſted with great privileges. At the period of the Norman ſurvey it enjoyed the ſame exemption from taxes as London, York, and Wincheſter. Since that time it has obtained many charters, and grants of immunities, from ſeveral monarchs. In the reign of Henry I. the fee-farm rents were granted to Matilda his queen; and in king John's time, Iſabel, his conſort, held Exeter in dower, with a fair thereunto belonging. In the third year of John's reign, the burgeſſes paid a fine of 110 marks for a confirmation of their charters; and about this period the city, which had been previouſly governed by port-reves and bailiffs, was incorporated, and had a mayor for its chief officer. We find in the Notitia Parliamentaria, that "in the reign of Edward I. the burgeſſes and citizens pleaded that their city was an ancient demeſne, and that they held it in fee-farm of the crown, paying 39*l.* 15*s.* 3*d.* To ſupport this claim, they referred to Henry III.'s charter, made to his brother Richard, king of the Romans; whereby they further challenged return of writs, a gallows, pillory, &c. and a fair of four days, beſides three weekly markets; which liberties they certified they enjoyed ſince the time of the conqueſt; upon which they were allowed." Henry VIII.

conſtituted Exeter a county of itſelf; thus rendering it independent of Devon, and inveſting it with correſponding privileges.

The corporation now conſiſts of a mayor, twenty-four aldermen, a recorder, chamberlain, town-clerk, ſheriff, four ſtewards, and ſeveral inferior officers. The corporate bodies within the city are thirteen, each of which is governed by officers annually choſen from among themſelves. Exeter was one of the firſt cities that returned members to parliament: the right of election is veſted in the magiſtrates and freemen, who are ſuppoſed to amount to about one thouſand perſons. The trade of Exeter is extenſive; yet would probably have been much more ſo, but for a contention between the inhabitants and Hugh Courtenay, earl of Devon, which deprived the city of the uſe of its river for navigable purpoſes during ſeveral centuries. The diſpute is reported by Izacke to have ariſen about ſome pots of fiſh; which, being expoſed for ſale in the market place, were ſeen nearly at the ſame time by the cators of the earl, and of the biſhop of Exeter, both of whom wanted the whole. The mayor, to whom the difference was referred, adjudged one part to the earl, another to the biſhop, and the third he directed to be kept for the uſe of the market. This deciſion, and a ſubſequent determination of the mayor and council, that no freeman of Exeter ſhould wear any foreigner's livery, badge, or cognizance without the mayor's licence, offended the earl, who immediately impeded the navigation of the river, "ſtopping, filling, and quirting the ſame," ſays Hooker, "with great trees, timber, and ſtones, in ſuch ſort, that no veſſel, or veſſels, could paſſe or repaſſe." Previouſly to this occurrence the tides flowed beyond the city; but now they only reach Topſham, a town between three or four miles nearer the ſea, the advantage of which was probably the chief object of the earl's meaſures, as that place was part of his eſtate, and became exceedingly flouriſhing in conſequence. The river was ſo completely choaked up, that though many attempts were made to reſtore the navigation, ſcarcely any thing was accompliſhed till the year 1675, when a canal was cut from Topſham to the city; and about twenty years afterwards the preſent haven was conſtructed: and by means of ſluices and flood-gates, veſſels of 150 tons burthen are now admitted to a good quay, formed near the city walls.

Exeter is ſituated 170 miles W. from London. The number of inhabitants, as returned under the late act, was 17,388; of houſes 2836. The principal employ of the labouring claſſes of people ariſes from the woollen trade; and the city has derived immenſe profits from the exportation of ſerge, kerſeys, and other articles, the value of which together has been computed at the average ſum of 600,000*l. per annum*: the chief markets were, during peace, Spain, Portugal, Germany, and Italy. About 300 perſons are alſo employed in manufacturing cotton, at a large factory eſtabliſhed on the banks of the river. Exeter had anciently a mint, which was granted by king Athelſtan; and money has been coined here ſo late as the reign of William III., the place of coinage being denoted by the letter E under the buſt.

This city has been the birth place of ſeveral very eminent and learned men. Among the moſt diſtinguiſhed are, Joſephus Iſcanus, whoſe writings adorned the commencement of the thirteenth century: John Hooker, ſir William Petre, and ſir Thomas Bodley, who all flouriſhed in the ſixteenth century; and ſir Peter, afterwards lord King, who held the high office of lord chancellor from 1725 to 1733.

In the vicinity of Exeter are ſeveral handſome, and reſpectable ſeats, belonging to the nobility and gentry. The principal of theſe are, Powderham-caſtle, belonging to viſcount Courtney; Mamhead, the ſeat of lord Liſburne; Haldon-houſe, the ſeat of ſir Lawrence Palk, &c.; Mount-Radford, the ſeat of John Baring, eſq.; Peamore, the ſeat of Samuel Kekewich, eſq.; Cleve, the ſeat of Thomas Northmore, eſq.; Cowicke, the ſeat of James White, eſq.; Oxton-houſe, the ſeat of the Rev. John Swete. Polwhele's Hiſtory of Devonſhire, 8vo. Jenkins's Hiſtory and Antiquities of Exeter, 12mo. 1806.

Exeter, a poſt-town of America, in the county of Rockingham and ſtate of New Hampſhire, and, Portſmouth excepted, the moſt conſiderable ſea-port town in the ſtate. It is ſituated on the head of the navigation on Swamſcot, or Exeter river, a branch of the Piſcataqua, 15 miles S.W. of Portſmouth. The tide riſes here eleven feet. This town is well ſituated for manufactures, and has already ſix ſaw mills, a fulling mill, ſlitting mill, paper mill, ſnuff mill, two chocolate and ten griſt mills, iron-works, and two printing offices. The ſadlery buſineſs is very conſiderable. Some few veſſels of different burden are built here, and the river is capable of floating thoſe of 500 tons. The ſituation of Exeter is adapted for an extenſive population. The public edifices are, two congregational churches, an elegant building appropriated to the academy, a handſome and capacious court-houſe, and a gaol. The public offices of the ſtate are at preſent kept in this place. It contains 1727 inhabitants. The townſhip is of an irregular figure, and about four miles ſquare. It was incorporated in 1638, before which period it was called Swamſcot falls; it lies 50 miles N. of Boſton. N. lat. 42° 59′. W. long. 71°. The academy was founded and endowed by the Hon. John Phillips, L.L.D. of Exeter, and incorporated by act of aſſembly in 1781. It is ſaid to be a reſpectable inſtitution, under the inſpection of a board of truſtees, and the immediate government and inſtruction of a preceptor and an aſſiſtant. Its annual income is 480*l.* and the number of ſtudents is commonly between 60 and 80. In 1794 a building was erected, which, in point of convenience, and perhaps of elegance, is exceeded by few buildings of the kind in the United States. Morſe.

Exeter, the north-weſternmoſt townſhip in Waſhington county, and ſtate of Rhode iſland, in which the ſeveral branches of Wood river unite; containing 2476 inhabitants, of whom 24 are ſlaves.—Alſo, a townſhip in Luzern county, Pennſylvania, including 737 inhabitants.—Alſo, a town in New Hanover county, in Wilmington diſtrict, North Carolina; ſituated on the N.E. branch of Cape Fear, about 36 miles from Wilmington.

EXFOLIATION. This term, in *Surgery*, denotes the proceſs by which the dead part of a bone ſeparates from the living portion. It is alſo not uncommon for ſurgeons to ſignify, by the word *exfoliation*, the piece of bone itſelf that has periſhed, though this is certainly an abuſe of language.

Exfoliation, or the ſeparation of a dead portion of bone from the living, is effected much in the ſame way as a ſlough is thrown off from the ſoft parts. The piece of bone which has periſhed is not detached by becoming rotten; for, in fact, it poſſeſſes conſiderable firmneſs, and at firſt coheres as intimately as ever to the living bone immediately contiguous to it. As Mr. Hunter has accurately obſerved, if the proceſs of exfoliation were not to take place, the dead piece of bone would remain undetached for years, inaſmuch as putrefaction is concerned in producing the ſeparation.

The more the pathologiſt conſiders the diſeaſes of the bones, the more he will find them reſemble thoſe of the ſoft parts. This fact, indeed, anatomy would lead one to infer, ſince the texture of the bones is the more ſimilar to the ſtructure of the reſt of the body, than an uninformed perſon would ſuppoſe. The chief difference is, that the bones contain lime, which the ſoft parts do not.

Mr. Hunter deſcribes the proceſs of exfoliation as follows; a dead bone (he ſays) acts on the ſyſtem in the ſame manner as any other extraneous body. It ſtimulates the adjacent living parts, in conſequence of which ſuch a proceſs is begun, as muſt end in the dead piece being thrown off. The effects of this ſtimulus are; firſt, that the living adjacent bone becomes more vaſcular, a circumſtance which always takes place, when a part has more to do than is juſt ſufficient for the ſupport of life. Secondly, that the earth of the living part, when it is in contact with the dead bone, is abſorbed. Hence the bone becomes ſofter, and is now only adherent by the animal matter in its texture. Thirdly, that the living animal part is at laſt abſorbed along the ſurfaces of contact. This part of the proceſs begins long before the laſt is finiſhed. Both of them begin firſt at the ſurface, though, in their courſe, they do not every where take place, in an equal degree, at the ſame time. Fourthly, that, in proportion to the waſte made by the laſt part of the proceſs, a fungus ariſes from the living ſurface, and fills up the intermediate ſpace, ſo as to prevent a vacuum. Mr. Hunter obſerves, that theſe different ſtages, taken together, conſtitute ulceration. He remarks, that when any part of a bone is once looſe, it will be puſhed towards the ſurface of the body, as moſt other inanimate ſubſtances are. This part of the proceſs is partly mechanical, and partly a continuation of ulceration. The ſame diſtinguiſhed ſurgical writer alſo notices, that a proof of the third ſtage above mentioned, may be derived from certain caſes, in which people die while exfoliation is going on. A ſmall groove, or worm-eaten canal, may then be diſcovered, which becomes gradually deeper, and follows the irregularities of the dead and living ſurfaces. After the application of the trepan, a circular piece of bone is frequently thrown off, which is always leſs than the ſpace from which it came. This, ſays Mr. Hunter, could never be the caſe, if there were not a loſs of ſubſtance.

Thus we find that exfoliation, and the proceſs by which a ſlough of the ſoft parts is detached, are nearly alike. In both inſtances, the matter which forms the bond of connection between the dead and living ſubſtances, is abſorbed, the dead part is looſened, and is next puſhed off by the riſing of the granulations.

The bones, on which exfoliations moſt frequently occur, are ſuch as are of a firm, ſolid ſtructure; thoſe which are of a ſpongy cellular texture, are more ſubject to the affection called caries.

All the old ſurgical practitioners and writers uſed to promulgate the doctrine, that whenever the ſurface of a bone was laid bare, and deprived of its perioſteum, an exfoliation muſt inevitably follow. The practice, which was reſorted to in conſequence of this notion, did really, for the moſt part, occaſion a deſtruction of a part of the bone, and the progreſs of the caſe ſeemed a confirmation of the erroneous opinion, reſting on experience itſelf for its foundation. For it followed almoſt as a matter of courſe with the ancient ſurgeons that ſince they conſidered the occurrence of exfoliation unavoidable in the circumſtance which we have mentioned, their grand aim was to promote and accelerate the proceſs, ſo as to ſhorten, as they conceived, the duration of the caſe. With this view, they uſed to put on the uncovered part of the bone ſtimulating, drying, ſpirituous applications, and, very often, the actual and potential cautery. Alſo, fancying that the wound could never heal till the dead piece of bone had come away, they uſed to avoid laying down the fleſh, ſo as not to leave the ſurface of the bone a long while expoſed, a cauſe, of itſelf, quite adequate to the production of an exfoliation.

However, the fact is, that a mere temporary expoſure of part of a bone, ſuch a tranſient denudation, as need only be permitted in caſes of wounds, is not neceſſarily, or even commonly followed by an exfoliation, when a proper method of treatment is purſued.

We have already remarked that the diſeaſes of the bones are more like thoſe of the ſoft parts, than many would imagine. The expoſed ſurface of a bone will not die, if it be otherwiſe free from injury, and the ſurgeon, immediately he is called, take care to lay down the detached fleſh in the ſituation which it previouſly occupied. Even when the denuded bone, on account of loſs of ſubſtance, cannot be directly covered again, it will not always exfoliate, provided the ſurgeon, inſtead of uſing the cautery, cauſtics, ſpirituous, or any other irritating applications, applies only ſome plain ſoft lint, or a pledget of any mild ſimple ointment.

When the ſoft parts are merely divided, the expoſed ſurface will not ſlough; but when the wound is complicated, with a violent degree of contuſion, laceration, &c. the caſe is different, and the fibres, veſſels, &c. moſt injured, will die and be thrown off. Theſe parts may either be killed at once by the violence, or the miſchief which they have ſuſtained may give riſe to inflammation, which may terminate in ſloughing. Things are nearly the ſame with reſpect to the bones. We will bring to our conſideration a few circumſtances relating to the ſubject of wounds of the head, which are, perhaps, more frequently than any other kind of wounds followed by exfoliations. In theſe inſtances, if the ſoft parts be ſimply cut, ſo as to occaſion an expoſure of the cranium, without the bone itſelf being violently contuſed, the wound may be healed by the firſt intention, and no part of the ſkull will exfoliate. The ſame occurrences may happen, together with a detachment of the pericranium, and yet the ſame conſequences will follow.

However, when the external violence has affected the bone, as well as the ſoft parts, the injured part of the ſkull will frequently die and exfoliate, notwithſtanding the moſt judicious treatment.

The proceſs by which an exfoliating piece of bone is thrown off, depends almoſt entirely upon nature, and the ſurgeon can interfere very little, with any real utility. The milder and leſs irritating his dreſſings are, the better. Sometimes, when the dead part of the bone is looſe, but is ſo covered with fleſh that it cannot come away, the practitioner may greatly expedite the cure, by making a proper opening for the removal of the piece of bone that has exfoliated. Sometimes, when the proceſs of exfoliation is long and tedious, he may render eſſential aid by occaſionally introducing a pair of ſmall forceps into ſome ſinus leading down to the affected bone, and moving the exfoliating portion a little every now and then, ſo as to accelerate its ſeparation. This latter proceeding, it is obvious, is only admiſſible when the opening in the ſoft parts is large enough, and when the dead piece of bone either projects, or is of ſuch a ſhape as will allow of its being taken hold of with a pair of forceps. Sometimes, when the dead piece of bone is prevented from exfoliating, by being overlapped by new oſſeous matter at its circumference, the ſurgeon may properly make ſome attempt to cut away the portion which is ſo wedged, that its ſpontaneous detachment would require an unreaſonable length of time. Endeavours of this kind, however, on the part of the ſurgeon, ſhould be made with great circumſpection and prudence; and, indeed, they can only be juſtifiable when the affected bone is ſufficiently ſuperficial.

EXFOLIATIVUM, from *exfolio, to ſhed the leaf*, an inſtrument for ſcraping or exfoliating bones.

EXFREDIARE, in our *Old Writers*, denotes the breaking of the peace, or committing open violence. Leg. Hen. I. cap. 31.

The word is formed from the Saxon, *frede*, *peace*.

EX GRAVI QUERELA, in *Law*, a writ that lies for him to whom any lands or tenements in fee are deviſed by will (within any city, town, or borough, wherein lands are deviſeable by cuſtom), and the heir of the deviſor enters, and detains them from him. (Reg. Orig. 244. Old Nat. Br. 87.) And if a man deviſes ſuch lands or tenements unto another in tail, with remainder over in fee, if the tenant in tail enter, and is ſeiſed by force of the intail, and afterwards dieth without iſſue, he in the remainder ſhall have the writ, ex gravi querela, to execute that deviſe. (New Nat. Br. 441.) Alſo where a tenant in tail dies without iſſue of his body, the heir of the donor, or he who hath the reverſion of the land, ſhall have this writ in the nature of a *formedon in the reverter*. Ibid.

If a deviſor's heir be ouſted by the deviſee, by entry on the lands, he may not afterwards have this writ, but is to have his remedy by the ordinary courſe of the common law. (Co. Litt. 111.) If the claimant's title accrues within 20 years, the moſt eligible method of proceeding, is now by *ejectment*; which ſee.

EXHÆREDATIO. See Exheredation.

EXHALATION, a fume or ſteam exhaling or iſſuing from a body, and diffuſing itſelf in the atmoſphere.

The terms exhalation and vapour are ordinarily uſed indifferently, but the more accurate writers diſtinguiſh them; appropriating the term vapour to the moiſt fumes raiſed from water and other liquid bodies; and exhalation to the dry ones emitted from ſolid bodies, as earth, fire, minerals, ſulphurs, ſalts, &c. In this ſenſe, exhalations are dry ſubtile corpuſcules, or effluvia, looſened from hard terreſtrial bodies, either by the heat of the ſun, or the agitation of the air, or ſome other cauſe, and emitted upwards to a certain height of the atmoſphere, where, mixing with the vapours, they help to conſtitute clouds, and return back again into dews, miſts, rains, &c.

Sir Iſaac Newton takes true and permanent air to be formed from the exhalations raiſed from the hardeſt and moſt compact bodies. See Air, Damp, Evaporation, and Vapour.

EXHAUSTED Receiver, a glaſs, or other veſſel, applied on the plate of an air-pump, and having the air extracted out of it by the working of the engine. (See Air-*pump*.) Things placed in an exhauſted receiver, are ſaid to be *in vacuo*. See Vacuum.

EXHAUSTIONS, in *Mathematics*. Method of exhauſtions is a way of proving the equality of two magnitudes, by a *reductio ad abſurdum*; ſhewing, that if one be ſuppoſed either greater or leſs than the other, there will ariſe a contradiction. The method of exhauſtions was of frequent uſe among the ancient mathematicians, as Euclid, Archimedes, &c. It is founded on what Euclid ſays in his tenth book, *viz.* that thoſe quantities whoſe difference is leſs than any aſſignable quantity, are equal; for if they were unequal, be the difference ever ſo ſmall, yet it may be ſo multiplied, as to become greater than either of them; if not ſo, then it is really nothing.

This he aſſumes in the proof of prop. 1. book x. which imports, that if, from the greater of two quantities you take more than its half, and from the remainder more than its half, and ſo continually, there will, at length, remain a quantity leſs than either of thoſe propoſed.

On this foundation it is demonſtrated, that if a regular polygon of infinite ſides be inſcribed in or circumſcribed about a circle, the ſpace, which is the difference between the circle and the polygon, will by degrees be quite exhauſted and the circle become equal to the polygon.

EXHEBENUM, in *Natural Hiſtory*, the name of a white and ſmooth ſtone, uſed by the ancient artificers in poliſhing gold. It ſeems to be the ſame with the lapis Samius, a ſmall ſmooth ſtone which they often found in the Samian earth.

EXHEREDATION, Exhæredatio, in the *Civil Law*, with us ordinarily called diſinheriting, is the father's excluding his ſon from inheriting his eſtate.

There are fourteen cauſes of exheredation expreſſed in Juſtinian's Novel; without ſome one of which cauſes, he decrees the exheredation null, and the teſtament inofficious, as the civilians call it.

Indeed, by the ancient Roman law, the father might pronounce exheredation without any cauſe; but the rigour of this law was reſtrained and moderated by Juſtinian.

EXHIBIT, in *Law*. When a deed, acquittance, or other writing is, in a chancery ſuit, exhibited, to be proved by witneſs, and the examiner writes on the back, that it was ſhewed to the witneſs at the time of his examination; this is called an exhibit.

EXHIBITION, a producing or ſhewing of titles, authorities, and other proofs of a matter in conteſt.

Anciently, they uſed the phraſe, exhibition of a tragedy, comedy, or the like; but now we ſay repreſentation in lieu thereof.

Exhibition, *Exhibitio*, in our *Old Writers*, is uſed for an allowance of meat and drink, ſuch as was cuſtomary among the religious appropriators of churches, who uſually made it to the depending vicar. The benefactions ſettled for the maintaining of ſcholars in the univerſities, not depending on the foundation, are alſo called exhibitions.

EXHORTATION, Hortatio, in *Rhetoric*, differs only from *ſuaſion*, in that the latter principally endeavours to convince the underſtanding, and the former to work on the affections.

EXHUMATION, of *ex*, *out of*, and *humus*, *ground*, the act of digging up a body interred in holy ground, by the authority of the judge.

In France, the exhumation of a dead body is ordered, upon proof that he was killed in a duel. By the French laws, a parſon has a right to demand the exhumation of the body of one of his pariſhioners, when interred out of the pariſh without his conſent.

EXIDEUIL, in *Geography*, a town of France, in the department of Dordogne, and chief place of a canton, in the diſtrict of Perigueux; 18 miles N. E. of Perigueux. The place contains 870, and the canton 8378 inhabitants, in 15 communes, and on a territorial extent of 190 kiliometres.

EXIGENCE, or Exigency, that which a thing requires, or which is expedient and ſuitable thereto.

EXIGENT, or Exigi Facias, in *Law*, a writ which lies where the defendant, in a perſonal action, cannot be found, nor any thing of his within the county, whereby to be attached, or diſtrained. It is directed to the ſheriff, ordering him to proclaim and call the party five county-court days ſucceſſively, and charge him to appear, under pain of outlawry.

The ſame writ alſo lies in an indictment of felony, where the party indicted cannot be found.

It is called an exigent, becauſe it exigit, *i. e.* exacts, or requires the party to appear, or, by forthcoming, to anſwer the law. If he appear not at the laſt day's proclamation, he is ſaid to be *quinquies*, or *quinto exactus*, and then is outlawed. See OUTLAWRY.

EXIGENTERS, four officers of the court of common pleas, who make all exigents and proclamations, in all actions where the proceſs of outlawry lies.

Anciently, the making writs of *ſuperſedeas* upon ſuch exigents as paſſed in their offices, did likewiſe belong to them; but this branch of buſineſs was taken from them under king James I. and committed to a particular officer in the court of common pleas, created by patent. See SUPERSEDEAS.

EXILE, BANISHMENT. See BANISHMENT.

Among the Romans, the word exile, *exilium*, properly ſignified an interdiction or excluſion from water and fire; the neceſſary conſequence of which was, that the interdicted perſon muſt betake himſelf into ſome other country, ſince there was no living without fire and water. Thus Cicero ad Herenn. obſerves, that the form of the ſentence did not expreſs exile, but only *aquæ & ignis interdictio*. See INTERDICTION.

The ſame author remarks, that exile was not properly a puniſhment, but a voluntary flying, or avoiding the puniſhment decreed: "Exilium non eſſe ſupplicium, ſed perfugium, portuſque ſupplicii." Pro Cæcina.

He adds, that there was no crime among the Romans, as among other nations, puniſhed with exile; but exile was a recourſe people flew voluntarily to, in order to avoid chains, ignominy, ſtarving, &c.

The Athenians frequently ſent their generals, and great men into exile, out of envy of their merits, or diſtruſt of their too great authority.

EXILE is ſometimes alſo uſed for the relegating a perſon into a place, whence he is obliged not to ſtir without leave.

The word is derived from the Latin *exilium*, or from *exul*, a baniſhed perſon; and that, probably, from *extra ſolum*, out of his native ſoil.

Figuratively, we uſe the phraſe, *honourable exile*, for an office, or employment, which obliges a man to reſide in ſome remote or diſagreeable place.

Under the reign of Tiberius, remote employments were a kind of myſterious exiles. A biſhopric, or even a lord-lieutenancy, in Ireland, has been ſometimes deemed a kind of exile. A reſidence, or embaſſy, in ſome barbarous country, is alſo a ſort of exile. Accordingly, it is ſaid, that the king cannot even conſtitute a man deputy, or lord-lieutenant of Ireland, nor make one a foreign ambaſſador againſt his will, ſince theſe in reality might be no more than honourable exiles. 2 Inſt. 46.

EXILES, in *Geography*, a town of France, in the department of the Po, on the river Doria; 5 miles W. S. W. of Suſa. This town was fortified, and guarded one of the paſſes into Piedmont; but by the treaty of peace between the French republic and the king of Sardinia, in 1796, the fortifications were to be razed.

EXILIUM, in *Law*, ſignifies a ſpoiling; and, by the ſtatute of Marlbridge, it ſeems to extend to the injury done to tenants, by altering their tenure, ejecting them, &c. And this is the ſenſe that Fleta determines; who diſtinguiſhes between vaſtum, deſtructio, and exilium. For he tells us, that vaſtum and deſtructio are almoſt the ſame, and are properly applied to houſes, gardens, or woods; but exilium is when ſervants are enfranchiſed, and afterwards unlawfully turned out of their tenements. Flet. lib. i. cap. 11. Stat. Marlb. cap. 25.

EXIMA, in *Geography*, a tribe or kabyle in the province of Suſa, in the ſouthern diviſion of Morocco; amounting to about 11,000 perſons.

EXIMENO, ANTONIO, in *Biography*, a Spaniſh Ex-Jeſuit, who had reſided at Rome many years, and publiſhed in that city, in 4to. 1744, a work, intitled "Dell' Origene e della Regole della Muſica," in which, too confident of his own powers, he imagined himſelf capable, with four years ſtudy only, intuitively to frame a better ſyſtem of counterpoint than that upon which ſo many great muſicians had been formed. Poſſeſſed of eloquence, fire, and a lively imagination, his book has been called in Italy, "a whimſical romance upon the art of muſic, in which is diſcovered a rage for pulling down, without the power of rebuilding." The author has certainly, with ſhrewdneſs and accuracy, ſtarted ſeveral difficulties, and pointed out imperfections in the theory and practice of muſic, as well as in the particular ſyſtems of Tartini and Rameau; but his own reſources and experience are totally inſufficient to the taſk of correcting the errors of the old ſyſtem, or forming a new one that is more perfect. He has more eloquence of language than ſcience in muſic. His reaſoning is ingenious and ſpecious, even when his data are falſe; but his examples of compoſition are below contempt; and yet, they are courageouſly given as models for ſtudents, ſuperior to thoſe of the old great maſters of harmony.

When Sig. Eximeno calls fugues and canons Gothic compoſitions, he does not diſgrace their ſtructure any more than he would our cathedrals, by calling them Gothic buildings. Let fugues be baniſhed from the theatres and private concerts, if he pleaſes, and let them remain in the church as a diſtinct ſpecies of compoſition, where they were firſt generated, and where they can never become vulgar or obſolete. The ſtyle being naturally grave, requires muſical learning, and will, by the ſolemnity of the words and place of performance, continue to be reverenced and reſpected. It is allowed that variety is more wanted in muſic than in any other art, and by totally excommunicating canons and fugues from the church, the art will loſe one capital ſource of variety, as well as ingenuity; and intelligent hearers will be deprived of a ſolemn ſtyle of muſic, to be heard no where elſe.

EXINANITION, the ſame as evacuation.

EXISTENCE, that whereby a thing has an actual eſſence, or is ſaid *to be*, *eſſe*.

The notion of exiſtence is applicable not only to a created but an uncreated ſubſtance: but it muſt be added, that the exiſtence of created ſubſtances, and eſpecially corporeal ones, implies a reſpect to place, time, and even an efficient cauſe; whence the ſchoolmen generally define it, that whereby a thing is formally and extrinſically without [*extra*] its cauſes, and that here, and now.

Exiſtence and eſſence come very near the nature of each other; in effect, they only differ in that we have different manners of conceiving the ſame thing.

For, 1. Eſſence is uſually explained either by the firſt, nobleſt, and radical attribute of the thing, *e. gr.* that of body, by extenſion; that of mind by thinking, &c. or by ſpecifying all the intrinſic attributes; and exiſtence, either by ſpecifying all place and all time, as in that of God; or by ſpecifying ſome definite place, and time, together with the cauſe, as in the creatures.

2. The foundation and occaſion of this diſtinction is

this: that eſſence belongs to the queſtion, *What is it? Quid eſt?* but exiſtence to the queſtion, *Is it? An eſt?*

3. Exiſtence, neceſſarily pre-ſuppoſes eſſence, and cannot be conceived without it; but eſſence may be conceived without exiſtence; in that eſſence belongs equally to things that are in *potentia*, and *in actu*; but exiſtence only to thoſe *in actu*. Note, however, that this does not obtain in God, about whoſe nature and eſſence the mind cannot think without conceiving his exiſtence.

We have divers ways of arriving at the knowledge of the exiſtence of things. Our own exiſtence we know by intuition; the exiſtence of a God, by demonſtration; and that of other things, by ſenſation.

As for our own exiſtence, we perceive it ſo plainly, that it neither needs, nor is it capable of any proof. In every act of ſenſation, reaſoning, or thinking, we are conſcious to ourſelves of our own being, and in this matter come not ſhort of the higheſt degree of certainty.

As to our knowledge of the exiſtence of a God, though he has given us no innate ideas of himſelf, yet, having furniſhed us with faculties of ſenſe, perception, and reaſon, we can never want a clear proof thereof. See GOD.

The knowledge of the exiſtence of other things, *i. e.* of external objects, bodies, a world, &c. we only have by ſenſation; for there being no neceſſary connection of real exiſtence with any idea a man hath in his memory, nor of any other exiſtence but that of God, with the exiſtence of any particular man; no particular man can know the exiſtence of any other being, but only when, by actually operating upon him, it makes itſelf be perceived by him. The having the idea of any thing in our mind, no more proves the exiſtence of that thing than the picture of a man evidences his being in the world, or the viſions of a dream make a true ſtory. It is, therefore, the actual receiving of ideas from without that gives us notice of the exiſtence of other things, and makes us know that ſomething doth exiſt at that time without us, which cauſes that idea in us, though we neither know nor conſider how it doth it.

This notice which we have by our ſenſes, of the exiſtence of things without us, though it be not altogether ſo certain as intuition and demonſtration, yet deſerves the name of knowledge, if we perſuade ourſelves that our faculties act and inform us right concerning the exiſtence of thoſe objects that affect them.

Now, beſides the aſſurance of our ſenſes themſelves, that they do not err in the information they give us of the exiſtence of things without us, we have other concurrent reaſons, as, 1. It is plain thoſe perceptions are produced in us by exterior cauſes affecting our ſenſes; becauſe thoſe that want the organs of any ſenſe never have the ideas belonging to that ſenſe produced in their minds. 2. Becauſe we find we cannot avoid having thoſe ideas, produced in our minds. When our eyes are ſhut, we can at pleaſure recal to our mind the ideas of light or the ſun, which former ſenſations had lodged in our memories; but if we turn our eyes towards the ſun, we cannot avoid the idea which the light or the ſun then produces in us, which ſhews a manifeſt difference between thoſe ideas laid up in the memory, and ſuch as force themſelves upon us, and we cannot avoid having; beſides, there is no one who doth not perceive the difference in himſelf between actually looking upon the ſun, and contemplating the idea he has of it in his memory; and therefore he hath certain knowledge, that they are not both memory or fancy. 3. Add to this, that many ideas are produced in us with pain, which we afterwards remember without the leaſt offence; thus, the pain of heat or cold, when the idea of it is received in our mind, gives us no diſturbance, which, when felt, was very troubleſome; and we remember the pain of hunger, thirſt, head ach, &c. without any pain at all, which would either never diſturb us, or elſe conſtantly do it, as often as we thought of it, were there nothing more but ideas floating in our minds, and appearances entertaining our fancies, without the real exiſtence of things affecting us from abroad. 4. Our ſenſes, in many caſes, bear witneſs to the truth of each other's report concerning the exiſtence of ſenſible things without us: he that doubts, when he ſees a fire, whether it be real, may feel it too if he pleaſes; and, by the exquiſite pain, may be convinced, that it is not a bare idea or phantom. Such is Mr. Locke's demonſtration of the exiſtence of external bodies.

The ingenious Dr. Berkeley has a different ſyſtem: external bodies, he contends, have no exiſtence, but in a mind perceiving them; that is, they only exiſt, *quatenus*, they are perceived; and of this he has given us what he and ſeveral others account a demonſtration.

In reality, "that neither our thoughts, paſſions, nor ideas formed by the imagination, exiſt without the mind, he obſerves, is allowed; and that the various ſenſations impreſſed on the mind, whatever objects they compoſe, cannot exiſt otherwiſe than in a mind perceiving them, is not leſs evident. This appears from the meaning of the term exiſt, when applied to ſenſible things. Thus, the table I write on, exiſts, *i. e.* I ſee and feel it; and were I out of my ſtudy, I ſhould ſay it exiſted; *i. e.* that were I in my ſtudy I ſhould ſee and feel it as before. There was an odour; *i. e.* I ſmelt it, &c. but the exiſtence of unthinking beings, without any relation to their being perceived, is unintelligible, their *eſſe* is *percipi*." The notion of bodies, he endeavours to ſhew, is founded on the doctrine of abſtract ideas: "What are light and colours, heat and cold, extenſion and figure; in a word, the things we ſee and feel, but ſo many ſenſations, notions, ideas, or impreſſions on the ſenſe? And is it poſſible to ſeparate, even in thought, any of theſe from perception? The ſeveral bodies, then, that compoſe the frame of the world, have not any ſubſiſtence without a mind: their *eſſe* is to be perceived or known; and as long as they are not perceived by me, nor any other thinking being, they have no ſhadow of exiſtence at all. The things we perceive are colour, figure, motion, &c. that is, the idea of thoſe things; but has an idea any exiſtence out of the mind? To have an idea is the ſame thing as to perceive; that, therefore, wherein colour, figure, &c. exiſt, muſt perceive them. It is evident, therefore, there can be no unthinking ſubſtance or ſubſtratum of thoſe ideas: but you may argue, if the ideas themſelves do not exiſt without the mind, there may be things like them, whereof they are copies or reſemblances, which exiſt without the mind; it is anſwered, an idea can be like nothing but an idea; a colour or figure can be like nothing elſe but another figure or colour. It may be farther aſked, whether thoſe ſuppoſed originals, or external things, whereof our ideas are the pictures, be themſelves perceivable or not? If they be, they are ideas; if they be not, I appeal to any one, whether it be ſenſe to ſay, a colour is like ſomewhat which is inviſible; hard or ſoft, like ſomewhat intangible, &c. Some diſtinguiſh between primary and ſecondary qualities; the former, *viz.* extenſion, ſolidity, figure, motion, reſt, and number, they maintain have a real exiſtence out of the mind; as for the latter, under which come all other ſenſible qualities, as colours, ſounds, taſtes, &c. they allow the ideas we have of them are not reſemblances of any things exiſting without the mind, or unperceived, but depend on the ſize, texture, motion, &c. of the minute particles of matter. Now, it is certain, that thoſe primary qualities are inſeparably united with the other ſecondary ones, and cannot even in thought be abſtracted from them, and therefore muſt only exiſt in the mind. Can any man conceive the extenſion and motion of a body without its other ſenſible qualities? For my part, I find it impoſſible to frame an idea of a body extended and moving, without giving it ſome colour, &c. In effect, extenſion, figure, and motion, abſtracted from all other qualities, are inconceivable; where the others, therefore, are, there theſe too muſt be, *i. e.* in the mind, and no where elſe. Again, great and ſmall, ſwift and ſlow, are allowed to exiſt no where without the mind, being merely relative and changing, as the frame or poſition of the organ changes: the extenſion, therefore, that exiſts without the mind, is neither great nor ſmall, the motion neither ſwift nor ſlow; *i. e.* they are nothing. That number is a creature of the mind, is plain (even though the other qualities were allowed to exiſt) from this; that the ſame thing bears a different denomination of number, as the mind views it with different aſpects; thus, the ſame extenſion is 1, or 3, or 36, as the mind conſiders it, with reference to a yard, a foot, or an inch. Nay, many of the modern geometricians hold, that a finite line may be divided into an infinite number of parts, and each of theſe infiniteſimals, into an infinity of others; and ſo on, *in infinitum*; ſo that the ſame thing is either unity or infinity, either no number or all number. In effect, after the ſame manner as the modern philoſophers prove colours, taſtes, &c. to have no exiſtence in matter, or without the mind; the ſame thing may be proved of all ſenſible qualities whatſoever: thus, they ſay, heat and cold are only the affections of the mind, not at all patterns of real beings exiſting in corporeal ſubſtances; becauſe the ſame body which ſeems cold to one hand, ſeems warm to another. Now, why may we not as well argue, that figure and extenſion are not patterns or reſemblances of qualities exiſting in matter; becauſe to the ſame eye, at different ſtations, or to eyes of different ſtructure, at the ſame ſtation, they appear various? Again, ſweetneſs, it is proved, does not exiſt in the thing ſapid, becauſe the thing remaining unaltered, the ſweetneſs is changed to bitterneſs, as in a fever, or by an otherwiſe vitiated palate. Is it not as reaſonable to ſay, that motion does not exiſt out of the mind? ſince, if the ſucceſſion of ideas in the mind become ſwifter, the motion, it is acknowledged, will appear ſlower, without any external alteration. Again, were it poſſible for ſolid figured bodies to exiſt out of the mind, yet it were impoſſible for us ever to know it: our ſenſes, indeed, give us ſenſation of ideas, but do not tell us that any things exiſt without the mind, or unperceived, like thoſe which are perceived: this the materialiſts allow. No other way therefore remains, but that we know them by reaſon's inferring their exiſtence from what is immediately perceived by ſenſe. But how ſhould reaſon do this, when it is confeſſed, there is not any neceſſary connection between our ſenſations and theſe bodies? It is evident, from the phenomena of dreams, phrenſies, &c. that we may be affected with the ideas we have now, though there were no bodies exiſting without them; nor does the ſuppoſition of external bodies at all forward us, in conceiving how our ideas ſhould come to be produced. The materialiſts own themſelves unable to conceive in what manner body can act on ſpirit, or how it ſhould imprint any idea on the mind. To ſuppoſe, therefore, bodies exiſting without the mind; is little elſe than to ſuppoſe God has created innumerable beings entirely uſeleſs, and ſerving to no purpoſe at all. On the whole it appears, that the exiſtence of bodies out of a mind perceiving them, is not only impoſſible, and a contradiction in terms; but, were it poſſible, nay real, it were impoſſible we ſhould ever know it. And again, that ſuppoſing that there are no ſuch things, yet we ſhould have the very ſame reaſon to ſuppoſe there were that we now have. Suppoſe, *e. gr.* an intelligence affected with the ſame train of ſenſations, impreſſed in the ſame order, and with the ſame vividneſs, would it not have all the reaſon to believe the exiſtence of bodies repreſented by his ideas that we have? All our ideas and ſenſations are viſibly inactive; nay, the very being of an idea implies paſſiveneſs and inertneſs; ſo that it is impoſſible for an idea to do any thing, or, in ſtrictneſs, be the cauſe of any thing; it cannot, therefore, be the reſemblance or pattern of any active being, unleſs oppoſites can be ſaid to reſemble one another. Now, we find a continual ſucceſſion of ideas of the mind; but theſe, it has been proved, do not depend on any external body as their cauſe; it remains, therefore, that their cauſe is an incorporeal active ſubſtance or ſpirit: for that I am not the cauſe of my own ideas, is plain from this, that when I open my eyes in broad day-light, I cannot help ſeeing various objects. Now, the fixed rules or methods wherein the mind we depend on excites in us the ideas of ſenſe, are called *laws of nature*; theſe we learn by experience, which teaches us, that ſuch and ſuch ideas are attended with ſuch and ſuch other ideas in the ordinary courſe of things. Ideas are not any how, and at random, produced; there is a certain order and connection eſtabliſhed among them like that of cauſe and effect; and there are ſeveral combinations of them made in a very regular artful manner, which we call *bodies*; and the ſyſtem of thoſe, *the world*. In ſtrictneſs, however, the connection of ideas does not imply the relation of cauſe and effect, but only of a mark or ſign of the thing ſignified: the fire I ſee is not the cauſe of the pain I feel, but the mark that forewarns me of it; the noiſe I hear is not the effect of this or that motion or colliſion of natural bodies, but the ſign thereof. The Carteſians own ſomewhat like this: the action of bodies on our organs, ſay they, is not the efficient cauſe of our ideas and perceptions, but only the occaſional cauſe, which determines God to act on the mind, according to the laws of the union of the ſoul and body." (See CAUSE.) Dr. Berkeley, indeed, taking away bodies, takes away what theſe philoſophers account the occaſions of their ideas: "by an occaſion, he ſays, muſt either be meant the agent that produces an effect, or ſomething obſerved to accompany or go before it in the ordinary courſe of things; but matter is allowed to be paſſive and inert, and cannot therefore be an agent or efficient cauſe; and this matter primitively, and in itſelf, is allowed imperceivable, and devoid of all particular ſenſible qualities; *i. e.* it has not this or that particular colour, this or that particular figure, &c. but has colour in the general, figure in the abſtract, &c. but an abſtract is no object of ſenſe; matter, therefore, cannot be the occaſion of our ideas in the latter ſenſe." See Berkel. Princip. of Human Knowl. See ABSTRACTION.

How far the great argument of the maintainers of a material world from the impoſſibility of God's deceiving us, and from the evidence that he does ſo, if there be no ſuch thing, will go againſt this reaſoning, we leave to the reader. See Stanl. Hiſt. Philoſoph. part xii. p. 816. where the objections of the ancient Pyrrhoniſt to the exiſtence of bodies are recited.

As to the exiſtence of ſpirits, Mr. Locke allows, that our having ideas of them does not make us know that any ſuch things do exiſt without us; or that there are any finite ſpirits, or any other ſpiritual beings, but God. We have ground from revelation, and ſeveral other reaſons, to believe with aſſurance, that there are ſuch creatures; but our ſenſes, being not able to diſcover them, we want the means of knowing their particular exiſtence; for we can no more know that there are infinite ſpirits really exiſting by the idea we have of ſuch beings, than by the ideas any one has of fairies or centaurs, he can come to know that things anſwering to thoſe ideas do really exiſt.

EXIT, properly expreſſes the departure of a player from off the ſtage, when he has acted his part.

The word is alſo uſed in a figurative ſenſe, to expreſs an kind of departure, even death.

EXITERIA, Eξιτηρια, in *Antiquity*, oblations or prayers to any of the gods for a proſperous expedition or journey. There were alſo feaſts under this denomination, which were celebrated by the Greeks, with ſacrifices and prayers, when their generals undertook expeditions againſt any enemy.

EXITURA, from *exeo*, *to come from*, in *Surgery*, an abſceſs which diſcharges matter.

EXITUS, Issues, in *Law*, the yearly rents or profits of lands or tenements. See Issue, &c.

EXLEGALITUS, the ſame with an outlawed perſon. See Outlaw.

EXLUNZA, in *Geography*, a town of Spain, in the province of Leon; 5 miles S.E. of Leon.

EX MERO MOTU, in *Law*, formal words uſed in the king's charters and letters patent, ſignifying that he does what is contained therein of his own will and motion, without petition or ſuggeſtion of any other.

The effect of theſe words is to bar all exceptions that might be taken to the inſtrument, by alleging that the prince in paſſing ſuch charter was abuſed by falſe ſuggeſtions.

EXMES, in *Geography*, a town of France, in the department of the Orne, and chief place of a canton in the diſtrict of Argentan; 9 miles E. of Argentan. The place contains 618, and the canton 7358 inhabitants, in 31 communes, and on a territorial extent of 147½ kiliometres.

EXMOUTH, though a watering place of conſiderable ſize and repute, is only a hamlet belonging to the pariſh of Littleham, in the county of Devon, England. As its name imports, it ſtands near the mouth of the river Exe. The buildings in general are low, but here are ſome good houſes inhabited by genteel families. The vicinity is highly pictureſque: from an eminence, called Chapel-hill, a line of coaſt preſents itſelf, which extends from Exeter to Berry-head, a diſtance of about twenty miles. This line is broken by ſeveral hills, behind which ſpring up ſome bold towering head-lands.

The plantations of Mamhead and Powderham-caſtle heighten the beauty of the proſpect; which is additionally embelliſhed by the noble buildings connected with thoſe eſtates. Holinſhed mentions a caſtle erected here to defend the entrance of the haven; and ſome ſlight veſtiges of embraſures are ſtill apparent. Exmouth is ſituated 168 miles W. from London; and contains, including the pariſh of Littleham, 432 houſes, and 1909 inhabitants, of whom 570 are returned as employed in trade or manufacture. Polwhele's Devonſhire, vol. ii.

EXOACANTHA, in *Botany*, from εξακανθουμαι, *to be armed with ſpines*; Mart. Mill. Dict. v. 2. Billard. Pl. Syr. faſc. 1. 10. Willd. Sp. Pl. v. 1. 1378. Claſs and order, *Pentandria Digynia*. Nat. Ord. *Umbellatæ*.

Gen. Ch. *General Umbel* of many ſpreading rays; the inner ones gradually ſhorter; the innermoſt extremely ſhort; *partial* of many rays. *General involucrum* moſtly of 12 channelled leaves, with ſpinous points; *partial* halved, its intermediate leaf very long, exactly like thoſe of the general involucrum. *Perianth* ſcarcely perceptible. *Cor.* uniform, of five equal, inflexed, heart-ſhaped petals. *Stam.* Filaments five, longer than the corolla; anthers roundiſh. *Piſt.* Germen inferior, ovate; ſtyles two, ſhort, ſtraight; ſtigmas ſimple. *Fruit* ſomewhat ovate, ſtriated, ſeparable into two parts. *Seeds* two, ovate, convex and ſtriated on the outſide, flat on the inner.

1. E. *heterophylla*. Billard. Syr. faſc. 1. t. 2. Gathered by M. La Billardiere near Nazareth. *Root* biennial, tap-ſhaped. *Stem* two feet, or more in height, ſlightly zig-zag, branched, round, ſtriated, leafy, ſmooth. *Leaves* pinnate, ſmooth; leaflets one or two pair with an odd one; thoſe of the radical leaves ovate, ſharply ſerrated, often cut; thoſe of the ſtem-leaves lanceolate, acute, narrow, entire, the odd ones very long. *Umbels* terminal, ſolitary, of about 40 rays; the partial ones of about as many, which are equal and crowded. The *involucral* leaves are very long, prominent, curved downwards, each ending in a ſharp ſpine. *Petals* white. *Anthers* yellowiſh. This plant is a-kin to the *Echinophora*, (ſee that article,) but differs generically in the want of a perianth, and in having all the flowers perfect and regular, with naked fruit, not imbedded in the involucrum.

EXOCARPUS, from εξ, *out of*, and καρπος, *a fruit*, becauſe the ſeed ſtands naked at the top of a fleſhy baſis or receptacle reſembling a pulpy fruit. Billard. Voy. Engl. ed. v 1. 167. t. 14. Claſs and order, *Polygamia Monoecia*, or rather, perhaps, *Pentandria Monogynia*. Nat. Ord. *Terebintaceæ*, Juſſ.

Gen. Ch. *Cal.* Perianth inferior, in five deep roundiſh, equal ſegments. *Cor.* none. *Stam.* Filaments five, inſerted into the calyx between its ſegments: anthers ſmall, roundiſh. *Piſt.* Germen ſuperior, globular; ſtyle, ſhort, ſolitary; ſtigma peltate, orbicular. *Peric.* none. *Seed* a roundiſh nut, of one cell, ſtanding on the top of an elliptical, hollow, fleſhy *receptacle*, about thrice its own ſize. Some flowers have an abortive germen, others have no ſtamens, all on the ſame plant.

Eſſ. Ch. Calyx inferior, in five deep ſegments. Corolla none. Stamens five. Piſtil one. Stigma peltate. Nut of one cell, ſtanding on a hollow fleſhy receptacle.

E. *cupreſſiformis*, the only known ſpecies, is an evergreen tree, found in New Holland by M. La Billardiere, as well as by Dr. White. It bears innumerable, compound, pendulous, angular, leafleſs *branches*, at whoſe extremities are ſituated the minute greeniſh *flowers*, produced in the month of May. The *fruit* is red, not unlike that of the yew in ſize, form, and colour, but the ſeed is perfectly expoſed to view. This plant has been raiſed from ſeed in England, but whether it ſtill remains in the gardens we know not. Its ſingularity entitles it to notice, and, we believe, it is by no means very tender, if not hardy enough to bear our winters in the open air.

EXOCATACŒLUS, in *Antiquity*, a general denomination, under which were included ſeveral grand officers of the church at Conſtantinople; as, the grand œconomus, grand ſacellarius, grand maſter of the chapel, grand ſcevophylax, or keeper of the veſſels, grand chartophylax, the maſter of the little chapel, and the protecdicus, or firſt advocate of the church.

There are many opinions with reſpect to the etymology of this term. F. Goar apprehends, that all the inferior prieſts were called Καταχοιλοι, *catacœli q. d.* people of a low condition, and that their ſuperiors were called exocatacœli, *q. d.* people out of the number of catacœli, or above them. Upon the whole, however, he adheres to the ſentiment of G. Coreſius, who ſays, that the patriarchal palace, and the apartments of the ſyncellus, and of the monks in the patriarch's ſervice, were in a very low part of the city which, with regard to the reſt, ſeemed a valley or pit; and that the officers above mentioned had their ſeveral houſes or palaces εξω, out of the valley; whence the name exocatacœli. M. Du-Cange derives the appellation from their being above the level or rank of the other clerks, and ſeated at church, &c. in more honourable places erected for that purpoſe on either ſide of the patriarch's throne.

The exocatacœli were of great authority: in public aſſemblies they had the precedence of biſhops; and in the patriarchate of Conſtantinople did the office of deacons, as the cardinals originally did in the church of Rome. Accordingly, in the letter of John IX. to the emperor Baſilius Leo, they are called cardinales.

At firſt they were prieſts; but ſome patriarchs of Conſtantinople, whom Codin does not mention, would have them for the future to be no more than deacons. The reaſon was, that being prieſts, each of them had their ſeveral churches, wherein they were to officiate on all the grand feſtival days; ſo that it unhappily fell out, the patriarch, on the moſt ſolemn days, was deſerted by all his chief miniſters.

EXO'CHAS, or Exóche, from εξω, *without*, and εχω, *to have*, in *Surgery*, a kind of excreſcence on the outſide of the anus.

EXOCIONITÆ, Exocionites, in *Church Antiquity*. The Arians were firſt called Exocionites, becauſe, when expelled the city by Theodoſius the Great, they retired into a place called Exocionium, and there held their aſſemblies. Juſtinian gave the orthodox all the churches of the heretics, excepting that of the Exocionites.

The word is derived from Εξακιονιον, or Εξωκιονιον, the name of the place above mentioned. Codin, in his Origines, ſays, that the Exocionium was a place encompaſſed with a wall, built and adorned by Conſtantine; and that without the circumference of the wall there was a column, with a ſtatue of that emperor, whence the place took its name, *viz.* from εξω, *without*, and κιων, *column*.

EXOCŒTUS, in *Ichthyology*, a genus of the abdominal kind of fiſhes; the head is ſcaly; mouth without teeth; jaws connected at each ſide; in the gill-membrane ten rays; body whitiſh; abdomen angulated; pectoral fins large, and formed for flying; anterior part of the rays carinated. Theſe are the flying fiſhes of Engliſh authors.

Species.

Volitans. Abdomen carinated each ſide. Linn. Amœn. Acad. *Exocœtus*, Gronov. *Winged flying fiſh*, Donov. Brit. Fiſhes.

This is an inhabitant of the American and Red ſeas, and alſo thoſe of the warmer parts of Europe: in one or more inſtances it has been known to appear as far north as Britain. The vaſtly diſproportionate magnitude of the pectoral fins in this genus of fiſhes affords them extraordinary advantage in effecting their eſcape when cloſely purſued by their voracious enemies in the water; but this facility of eſcape expoſes them oftentimes to the attacks of other adverſaries, and they not unfrequently elude the purſuit of the bonito, or the porpeſſe, in their native element, to become the prey of gulls, corvorants, and other aquatic birds that hover over the water to ſeize on them in their aerial flight. They remain only for a ſhort time ſuſpended in the air before they again dive into the water, and after a pauſe of a few moments emerge again at ſome diſtance. They often quit the water in ſhoals, and ſometimes alight on board ſhips in great numbers. The fleſh is occaſionally eaten.

The colour is ſilvery, with the back rather blueiſh; the pectoral fins blueiſh, edged with yellow; ventral fins and extremity of the tail ſometimes reddiſh.

Exiliens. Ventral fin reaching to the tail. Gmel. Bloch. *Swallow fiſh.*

A native of the Mediterranean and Red ſeas. The colour is ſilvery, blue on the back, with the fins yellowiſh at the baſe, with the extremity blueiſh. The fleſh is in eſteem.

Mesogaster. Ventral fins in the middle of the abdomen. Bloch. *Atlantic flying-fiſh.*

Native of the Atlantic ſeas, and was obſerved by Plumier about the coaſts of the Antilles. The fiſh is bright ſilvery, with the back and fins blueiſh. The ſpecies is ſufficiently diſtinguiſhed by the ſituation of the ventral fins.

Commersonii. Dorſal fin marked with a dark blue ſpot.

Cepede. *Commerſonian flying-fiſh.* Shaw Gen. Zool.

Deſcribed by Commerſon as reſembling the firſt ſpecies, except in having a dark blue ſpot on that part of the dorſal fin neareſt the tail, and the ventral fins placed beyond the middle of the abdomen, their tips reaching to about the middle of the anal fin.

The laſt mentioned ſpecies, we are inclined to believe, may not differ ſpecifically from the fiſh deſcribed by Bloch under the name of meſogaſter: the evolans and volitans of Linnæus, according to ſome writers, conſtitute but one ſpecies; and we ſhould alſo ſpeak with diffidence of the fiſh denominated exocœtus non volitans by Forſkal; is it a variety of volitans β, as Gmelin conſiders, or rather an error ariſing from ſome accidental circumſtance?

EXOCY'STE, or Exocy'stis, from εξω, *without*, and κυστις, *the bladder*. Writers define this term of ſurgery a prolapſus of the lining of the bladder. We are probably to underſtand by the word, a protruſion of the lining outward, between the faſciculi of the muſcular coat of this organ, an occurrence which we know does really ſometimes take place. Stones have been found protruded in this manner, carrying along with them a part of the lining of the bladder.

EXODIARY, Exodiarius, in the *Ancient Roman Tragedy*, was a droll, or mime, who appeared on the ſtage when the tragedy was ended, and performed what they called the exodium, or concluſion of the ſhew, to divert the company.

EXODIUM, Εξοδιον, in the *Ancient Greek Drama*, was one of the four parts or diviſions of a tragedy.

The word is formed from the Greek, εξοδος, *going out*, *digreſſion*, of εξ and οδος, *way*, *road*. Feſtus, lib. v. calls it *exitus*.

The exodium, according to Ariſtotle, was ſo much as was rehearſed after the chorus had ceaſed to ſing for the laſt time; ſo that exodium with them was far from being what the epilogue is with us, as ſeveral people have imagined it was.

The exodium was ſo much of the piece as included the cataſtrophe and unravelling of the plot; which cataſtrophe, &c. in pieces regularly compoſed, always began after the laſt ſinging of the chorus, anſwering nearly to our fourth and fifth acts. M. Dacier's Comment. on Ariſtotle's Poetics, chap. 12. See Catastrophe and Chorus.

Among the Romans the exodium was a different thing; it was pretty nearly what farces are with us. After the tragedy was over, came a pantomime on the ſtage, called the exodiarius, who, by his grimace, jeſting, and buffoonery, diverted the people, compoſed their minds, and wiped away the tears which the tragic ſpectacle had occaſioned to be ſhed.

Viginere on T. Livy ſays, the exodium conſiſted of certain

tain humorous drolling verſes, rehearſed by the youth at the end of the fabulæ atellanæ, and anſwering to our farces. In another place, the ſame author ſays, that the exodia were a kind of interludes in the intervals between the acts, partly fable and pleaſantry, partly muſic, &c. to give time both for the ſpectators and actors to recover breath. The paſſage in Livy, whence he takes the notion, is lib. vii. dec. 1. "Ridicula intexta verſibus, quæ juventus inter ſe more antiquo jactare cœpit, eaque conferta ſunt fabulis potiſſimum atellanis." See alſo Juvenal.

> "Urbicus exodio riſum movet Attellanæ
> Geſtibus Autonoes."

Exodium, in the *Septuagint*, ſignifies the end or concluſion of a feaſt.

The Hebrew text calls the day עערת, which the Seventy render Εξοδιον.

In particular, exodion is uſed for the eighth day of the feaſt of tabernacles, which, it is ſaid, had a ſpecial view to the commemoration of the Exodus, or departure out of Egypt, though there is nothing of it expreſſed in Scripture.

Exodium, was alſo the name of a ſong ſung at the concluſion of a meal or feaſt.

EXODUS, the ſecond of the five books of Moſes.

The word in its original Greek, Εξοδος, literally imports a *going out*, or *journey*; and was applied to this book, becauſe the hiſtory of the Iſraelites' paſſage out of Egypt is related therein. Beſides this, it contains the ſtory of what was tranſacted in Egypt from the death of Joſeph to the delivery of the Jews; as well as what paſſed in the wilderneſs, and particularly at mount Sinai, to the building of the tabernacle.

The Hebrews call it *veelle ſemoth*, q. d. *hæc nomina*, theſe are the initial words of the book; for the ſame reaſon they call Geneſis, *bereſith*, q. d. *in principio*, *in the beginning*.

EX OFFICIO, in *Law*, denotes a power which a perſon has in virtue of his office, to do certain things without being applied to; as a juſtice of peace may not only grant ſurety of the peace, at the complaint or requeſt of any perſon, but he may demand and take it, ex officio, at diſcretion, &c. Dalt. 270.

By a branch of ſtatute 1 Eliz. the queen, by her letters patent, might authorize any perſons exerciſing eccleſiaſtical juriſdiction to adminiſter an oath, ex officio, whereby ſuppoſed offenders were forced to confeſs, accuſe, or clear themſelves of any criminal matter, &c. but this branch relating to this oath is repealed by 17 Car. I. cap. 11.

Ex officio *Informations*. See Information.

EXOLICETUS, in *Natural Hiſtory*, a name uſed among the writers of the middle ages to expreſs a ſmall ſtone which had ſuch a variety of colours that it dazzled, as they ſay, people's eyes in looking at them. It is ſaid to have been found in Libya. The name is probably only a corruption of the hexacontalithos of Pliny and the older writers; and this ſeems to have been no other than a name for the opal.

EXOMIS, of εξ, *out of*, and ωμος, *ſhoulder*, in *Antiquity*, a ſtraight narrow garment through which the ſhoulders appeared. It had ſomething in common with the tunic, and ſomething with the pallium. It was worn by ſlaves, ſervants, and the lower claſſes of people among the Romans.

EXOMOLOGESIS, Εξομολογησις, formed of Εξομολογεω, *I confeſs*, a term little uſed but in ſpeaking of the ancient ceremonies of repentance, whereof the exomologeſis, by us called *confeſſion*, was a part.

Some of the ancients, and particularly Tertullian, De Pœnit. cap. 9. uſe the word in a greater latitude, as comprehending the whole of repentance.

A public exomologeſis was never commanded by the church for ſecret ſins, as may be ſeen in the capitulars of Charlemagne, and the canons of divers councils.

EXOMPHALOS, from εξ, *out*, and ομφαλος, *the navel*, in *Surgery*, an umbilical hernia, or a diſeaſe which conſiſts of a protruſion of ſome of the abdominal viſcera at the navel. The ſubject will be particularly conſidered in the article Hernia.

EXONCHOMA, from εξ, *out*, and ογχος, *a tumour*, any large prominent ſwelling.

EXONEIROSIS, from εξ, *out*, and ονειρος, *dream*, a nocturnal pollution or emiſſion of the ſemen in dreams. This, if it happens but rarely, is uſually a ſign only of redundant vigour; but if it happens frequently, is a ſign of weakneſs of the ſeminal veſſels, which is moſt frequently the caſe.

EXONERATIONE Sectæ, in *Law*, a writ that lay for the king's ward, to be freed from all ſuit to the county-court, hundred-court, leet, &c. during the wardſhip. F. N. B. 158.

EXONYCHOS, of εξω, *without*, and ονυξ, *a nail*, in *Botany*, a name given by ſome of the ancient writers, among whom are Dioſcorides and Pliny, to the gromwell or lithoſpermum. See Ægonychus.

EXOPHTHALMIA, from εξ, *out*, and οφθαλμος, *the eye*, in *Surgery*, a diſeaſe conſiſting of a protruſion, or a preternatural projection of the globe of the eye from the orbit, ſo that the part cannot be duly covered by the eye-lids. The diſorder may proceed either from a morbid enlargement of the eye-ball, or what, perhaps, is a ſtill more common cauſe, ſome tumour which occupies or diminiſhes the cavity of the orbit, and conſequently diſplaces the eye.

The affection has ſeveral other names beſides exophthalmia; as, for inſtance, buphthalmus, ophthalmoptoſis, prolapſus oculi, ecpieſmos, melon, &c.

From the few words already delivered on the ſubject, it is eaſy to perceive that exophthalmia may ariſe from a variety of cauſes, and muſt of courſe require very different modes of treatment in different caſes.

One cauſe of the diſorder noticed by writers, is a diſeaſe of the fat and cellular ſubſtances ſituated in the orbit, and ſerving as a ſupport to the eye-ball. In this caſe the ſurface of the eye appears more moiſtened with tears than uſual, and the fat and cellular ſubſtance becoming thickened and indurated, forces the eye-ball forward out of its ſocket. As the eye cannot now be properly covered and ſheltered by the eye-lids, it inflames, and ulcerates on its ſurface, and the patient becomes afflicted with very ſevere and deep-ſeated pain. This ſort of cauſe is as difficult of removal, when the diſeaſe has advanced to a certain extent, as it is difficult of detection at an early period of the caſe. The famous oculiſt, Saint Yves, pretends, however, to have ſometimes diſperſed ſuch thickenings of the cellular ſubſtance in the orbit by perſevering in the exhibition of calomel and purgative medicines. The ſame author aſſures us, that he ſucceſsfully exhibited the æthiops mineralis to a ſcrofulous patient for three months, whoſe eye-ball protruded to the extent of three lines, by reaſon of a morbid thickening of the cellular ſubſtance, and an enlargement of the lachrymal gland.

When the diſeaſe does not yield to any remedies, the ſymptoms may become ſo urgent as to render the extirpation of the eye indiſpenſably neceſſary, as is proved by the following caſe related by Saint Yves. A woman's eye-ball protruded out of its natural ſituation, in conſequence of a morbid thickening of the fat at the bottom of the orbit.

The diſeaſe was attended with inſupportable pain, and great reſtleſſneſs. The ſymptoms were appeaſed by the employment of general means, and the progreſs of the affection was for a time retarded. Three years afterwards, the eye having been left in a projecting condition, Saint Yves was requeſted to viſit the patient. She was now labouring under a violent fever, accompanied with ſevere head-ach. The globe of the eye was of a leaden colour, and exceedingly prominent, its coats being ſwollen, and appearing likely to become gangrenous. The medical practitioners who were in the habit of attending the woman were of opinion that the eye ought to be extirpated. The neceſſity for performing the operation, indeed, ſeemed to them ſo urgent, that the proceeding was immediately adopted. The febrile and all untoward ſymptoms ſubſided on the fourth or fifth day, and, in about three weeks, the cure was complete.

Exophthalmia may alſo be occaſioned by ſome tumour of the ſurrounding parts, either of thoſe within, or of others on the outſide of, the orbit. The celebrated French ſurgeon, M. Louis, met with a man, 40 years of age, in whom a carcinomatous fungus, ſituated in the antrum, had deſtroyed the bony plate which conſtitutes the bottom of the orbit, and puſhed the eye-ball almoſt entirely on the cheek, ſo as to produce a great deformity of the countenance. The upper jaw bone was carious, both towards the palate and noſe, and the patient periſhed of the afflicting complaints, brought on by the carcinomatous ulceration of all the diſeaſed parts. The exophthalmia was the effect of the prodigious ſize of the tumour, the growth of which could not be effectually reſiſted by the bones. The protruſion of the eye, ſays M. Louis, might have been prevented by attacking the firſt diſeaſe at a proper period, on the ſide towards the mouth. The growth of the cancerous fungus is repreſented by this diſtinguiſhed writer as the effect of a diſeaſe of the bone, which latter affection he deſcribes as the conſequence of ſyphilis, which had not been ſkilfully treated.

Raw makes mention of a child whoſe left eye was completely protruded from the orbit, and as large as one's two fiſts. The diſeaſe, which had only begun a few months before, proved fatal. On opening the cranium, a fungous ſwelling was diſcovered, the baſe of which was connected with the dura mater above the orbit, without any diſeaſe of the cerebrum.

Exophthalmia, however, originates ſtill more frequently from the enlargement of an exoſtoſis, which ariſes within the orbit, and forces the eye-ball out, in proportion as it increaſes in magnitude. When the bony ſwelling is ſituated near the edge of the orbit, the tumour may be attacked with beneficial effects, without meddling with the eye itſelf. The truth of what has juſt now been obſerved is illuſtrated by the following caſe. A woman, 30 years of age, had a fiſtula lachrymalis, for which ſhe had undergone an operation to no purpoſe. The bones became enlarged, and, fifteen years afterwards, an exoſtoſis of the os planum and internal angular proceſs of the os frontis had attained the ſize of an egg. The globe of the eye, being laterally compreſſed, was forced out of the orbit, and, in ſome meaſure, hung over that part of the cheek which was near the leſſer angle. M. Braſſant applied a cauſtic to the exoſtoſis; ſuppuration enſued, and in the courſe of three or four months an exfoliation of a conſiderable portion of the bony ſwelling took place, the eye reſumed its natural poſition, and the cure was completed a ſhort time afterwards.

Exophthalmia is ſometimes produced by the formation of a ſteatomatous, or ſchirrous tumour, at the bottom, or ſides of the orbit. Trincavelli, Bonnetus, and Saint-Yves, furniſh us with ſeveral examples of this ſort. Here an operation is requiſite; but a great deal of patience and dexterity are eſſential in its performance. As the recital of facts tends to the elucidation both of precept and practice, we ſhall offer an abridged account of a caſe, related by Dr. Hope, in the Philoſophical Tranſactions, where every thing reſpecting the method of treatment is very perſpicuouſly explained. A young woman, eighteen years of age, was affected, when twelve years old, with a diſtortion of her left eye, towards the temple. This circumſtance aroſe gradually, in conſequence of the growth of a tumour between the eye and the orbit. In a few years, the ſwelling protruded externally, in the form of a hard tumour, which extended from the greater angle nearly to the leſſer one, beneath the lower eyelid, and which reached nearly half an inch over the cheek. This tumour had puſhed almoſt the whole eye-ball out of the orbit, ſo that the pupil was removed more than three inches from its proper place. The eye was alſo much more prominent than the other, puſhed over the temple, and quite motionleſs, which circumſtances, together with the tumour, preſented a frightful appearance. The ſight, however, was not loſt. Dr Hope, though diſſuaded by Monro, undertook the cure of the patient in the year 1744. Having placed her in a convenient poſture, and made the integuments tenſe, he made an inciſion about an inch long, from the greater to the leſſer angle, following the direction of the fibres of the orbicularis palpebrarum muſcle. The lips of the wound being ſeparated, he next paſſed a crooked needle, armed with ſome ſilk, through the middle of the tumour, and, regularly as he cut all the adheſions with a biſtoury, he drew outward the whole maſs of the diſeaſe. Sciſſars were employed for dividing ſuch connections, as were the moſt deeply ſituated. The part which was thus cut out appeared to be furniſhed with a thick membranous ſubſtance, excluſively of the body of the tumour, which was of a regular, ſpherical, ſmooth form, and about as large as a ſmall pigeon's egg; the interior was of a fleſhy ſtructure. In detaching the ſwelling from its adheſions, ſeveral callous indurations were met with, attached to the globe of the eye. The tumour being extirpated, Dr. Hope introduced his finger to the bottom of the orbit, where he felt ſeveral hardneſſes and calloſities ſtill remaining; he kept his finger there, and having by this means paſſed in a needle and ligature, he drew them through the baſe of the calloſities. Now having directed an aſſiſtant to hold up the ligature, he paſſed in the point of a pair of ſciſſars, on the end of his finger, and made two or three ſtrokes with them, in the place where he felt the roots of the callous hardneſſes. Thus he ſucceeded in cutting away the whole of the indurated parts, ſo as to leave the bottom of the orbit, as far as he could aſcertain, perfectly ſmooth and free from calloſity. All the time that the operation laſted, no hæmorrage of any conſequence took place: only a large quantity of dark-coloured grumous blood was poured out from the varicous veſſels. The wound was dreſſed with ſome dry lint, which was not removed till the third day. The eyelids and tunica conjunctiva were affected with a flabby kind of ſwelling, attended with a ſlight inflammation and pain in the anterior part of the head. The dreſſings conſiſted of ſimple digeſtive and reſolvent applications. The pain in the head, and the tumefaction continued three days, without any formation of matter. Dr. Hope then touched the bottom of the wound with the lapis infernalis, and, a few hours afterwards, a large quantity of black blood was diſcharged. From this period the pain in the head, and the ſwelling ſubſided; there was alſo emitted, during the two ſucceeding days, a bloody ſanies, which occurrence induced Dr. Hope to make uſe of ſome injections of warm water, mixed with a little ſpirit of wine, and honey of roſes. After the adoption of this plan of treatment, the pus aſſumed a more favourable appearance. Such ſoft, fungous excreſcences as aroſe in the courſe of the cure, were deſtroyed with the lapis infernalis, and it was not long before the wound was entirely healed. The eye, however, remained unalterably immoveable; for the abductor muſcles had been ſo long contracted, while the adductors had been for ſo conſiderable a time ſtretched and tenſe, that they had completely loſt all power of action.

Finding, that by making rather forcible preſſure on the eye-ball, the part could be made to return, in a great degree, into the orbit, though it became protruded again as ſoon as ſuch preſſure was diſcontinued; Dr. Hope conceived, that a bandage which would conſtantly keep up a graduated compreſſion, might be attended with ſome benefit, and determine the muſcles more ſpeedily to reſume their proper tone, by maintaining the eye in its natural ſituation. Conformably to this idea, this gentleman cauſed a ſteel bandage to be conſtructed, with a concave plate proportioned to the convexity of the globe of the eye. This apparatus made preſſure on the ſide of the eye-ball next the temple, by means of a ſcrew. The machine was put on, after gently puſhing back the eye into its natural ſituation with the hand; and then laying a ſoft compreſs between the eye and the plate of copper, Dr. Hope uſed to make the preſſure act on the part by means of the ſcrew, in ſuch a way, that it was impoſſible for the eye to become diſplaced outward again, as it uſually was before. With the aid of this bandage, which the patient wore conſtantly, night and day, and which was gradually tightened more and more, the eye regained its natural poſition in the ſpace of about twenty days, and did not deviate from it again. At the time when the caſe was publiſhed, the eye was capable of motion in every direction, and the patient could ſee quite as well with it as the other. The wound got completely well in about a month, and only ſeven weeks elapſed before the cure was, in every reſpect, perfect.

Reſpecting the foregoing caſe, M. Louis obſerves, that it certainly does honour to the ſkill and intelligence of the gentleman who undertook the treatment.

Le Dran was equally ſucceſsful in the treatment of a ſimilar diſeaſe, though certainly it was not ſo conſiderable as the preceding. The means made uſe of, were the actual cautery and alternative medicines. The ſubject was a young lady, aged eighteen, who, from her infancy, had been ſubject to inflammations about her lips, eyes, and ears. She had had a fiſtula lachrymalis, and, ſome time after the uſual operation for this complaint, there originated, at the leſſer angle of the eye, a fungous excreſcence, which protruded from the orbit, and had been ſucceſſively removed with the knife, and touched with the lapis infernalis; but in vain, as the tumour always made its appearance again. This plan of treatment was not attended with any greater ſucceſs under the hands of Le Dran, and, conſequently, he ſoon made up his mind to attack the excreſcence, by introducing the actual cautery into its centre. For this purpoſe, he took a long, large, ſewing needle, and had it firmly fixed on a handle. The inſtrument, having been made red-hot in the flame of a wax-candle, was puſhed to the depth of about half an inch into the middle of the ſwelling. By repeating the application of the cautery three or four times, at intervals of a few days, Le Dran ſucceeded in deſtroying the tumour as deeply as its root, the action of the fire having extended beyond the parts actually touched with the heated needle. The conſequence was, that the ſwelling never grew again. To render this cure more certain, Le Dran, for a long while, kept the cauteriſed part open, and the patient was ordered to take alterative medicines, the chief of which were calomel and æthiops mineralis.

The two foregoing examples prove what ſurgery can accompliſh, when the diſeaſe is taken in time. However, when the proper kind of treatment has been deferred too long, the affection of the eye becomes of ſuch a deſcription, as to be irremediable. Nothing now remains to be done except extirpating, not only the tumour, but alſo the whole of the eye-ball. Even this formidable operation is often impracticable, particularly when the parietes of the orbit are diſeaſed. For the bones, in conſequence of the preſſure made upon them by the ſwelling, are rendered carious, and very foul ill-conditioned ulcers are produced. In this ſtate there can be but little hope of a recovery, whatever mode of treatment is adopted.

One ſpecies of exophthalmia, which is indeed uncommon, but not the leſs worthy of being known, is that which is occaſioned by an encyſted tumour. In the fourth volume of the Medical Obſervations and Inquiries, there is an inſtance recorded by Dr. Brocleſby. A labouring man of the pariſh of Haſelmere, in Surry, had been for ſeveral years afflicted with a pain and an obſcurity of ſight in one of his eyes. The affection continued, without much attention being paid to it, until, about two or three years afterwards, the man became quite blind on that ſide. At this period, the globe of the eye was protruded outward in ſuch a manner, that almoſt the whole of the inner ſurface of the lower eye-lid was turned out, and hung down over the cheek, ſo as to form a true ectropium.

Several ſurgeons who were conſulted adviſed the patient not to expoſe himſelf to the riſk of an operation, fearful that the diſeaſe might be converted into one of a cancerous nature. Notwithſtanding this counſel, the man did not ceaſe going about to have the advice of all ſuch perſons as ſeemed likely to afford him any aſſiſtance. At length, he applied to Mr. Dale Ingram, who, having carefully examined the diſeaſe, thought, that on compreſſing different places, he felt a decided fluctuation below the globe of the eye. He immediately ſuſpected, that the fluid was contained in a cyſt, and, conſequently, that the patient might receive relief from an operation. However, the above gentleman would not undertake any thing without conſulting Mr. Bromfield.

The latter ſurgeon, after a careful examination, was not againſt the probability of ſucceſs, and he did the operation in the following manner. After having covered the ſound eye, by tying a handkerchief round the head, and put the eye-lids of the affected eye as near together as poſſible, and directed them to be held in this poſition, Mr. Bromfield made an inciſion through the lower eye-lid to the conjunctiva, and thus made a ſufficient opening for the introduction of his finger behind the globe of the eye. In this way he was enabled to put in a very narrow ſharp-pointed knife, for the purpoſe of puncturing the ſubſtance, which was taken to be the cyſt. Mr. Bromfield was not deceived in his expectation; for, as ſoon as the opening was made, nearly a glaſsful of a thin tranſparent fluid was diſcharged. He now waited a little, both in order to give the patient an opportunity of waſhing out of his mouth ſome blood, which had got into it, and for the ſake of conſidering what ſteps could be taken to extirpate the cyſt, which had contained the fluid. At laſt, he determined to proceed as follows: he paſſed into the wound a double kind of tenaculum, with which he took hold of the cyſt, and then diſſected it entirely away. The wound was filled with ſoft lint, and the dreſſings were kept on with a ſuitable bandage.

In leſs than four and twenty hours there appeared on the ſame ſide of the face a conſiderable degree of ſwelling, which ſoon ſubſided, however, on a dilatation of the firſt wound being made, lighter dreſſings being put on, and the bowels opened. In leſs than a month the man got quite well, and returned to his home with infinite ſatiſfaction. Dr. Brocleſby obſerves, that Mr. Ingram was perſuaded, before the operation, that the muſcles would draw back the eye-ball into the orbit, and that even ſome degree of viſion might return. The doctor could hardly ſuppoſe all this poſſible; but, having an opportunity of ſeeing the man, about five months afterwards, he could ſcarcely recognize him. The eye-lids had recovered their original ſtate, and moved as well as thoſe of the oppoſite eye. The man alſo informed Dr. Brocleſby, that, for about the laſt month, he had begun to diſtinguiſh with the affected eye light from darkneſs, and that his power of ſeeing was becoming greater every day. Dr. Brocleſby remarks, that he could not find any caſe of this kind related by authors, except one very analogous inſtance, recorded by Saint Yves in his treatiſe on the diſeaſes of the eyes.

The laſt kind of exophthalmia which we have to notice, is that which Sauvages has termed *traumatic*. In this ſort of caſe, the eye is ſo much protruded from the orbit, that ſurgeons have frequently been induced to remove the diſplaced part altogether, and this ſometimes has been done too inconſiderately for the unfortunate patient. Covillard informs us, in his Chirurgical Obſervations, that he was called to ſee a man, againſt whoſe eye a racket-ball had been ſtruck with ſuch violence, that all the circumference of the globe of the eye was ſeparated from the orbit. A relation of the perſon who was hurt was ſtanding by with a pair of ſciſſars in his hand, ready to cut the reſt of the parts which connected the eye with the head. Covillard entered the room in time, and very fortunately, to reſiſt this proceeding, as a complete cure enſued without having recourſe to it. Indeed, ſuch was the ſucceſs, that the patient's power of ſeeing ſuffered no kind of diminution or impairment. A ſimilar inſtance, though ariſing from a very different cauſe, occurred to Mr. Benjamin Bell. The eye was almoſt knocked out of the orbit by the violence with which a pointed piece of iron had entered betwixt the ſocket and the eye-ball. The iron had paſſed through a portion of the orbit, and remained firmly fixed there for about a quarter of an hour. During the whole of this time, the patient ſuffered inſupportable pain. He had completely loſt the faculty of ſeeing, and the eye-ball protruded in ſuch a manner, that there was every reaſon to fear that the optic nerve was ruptured, and, conſequently, great doubt concerning the propriety of replacing the part, or not. However, as a little delay did not ſeem likely to be dangerous, it was determined to wait a little. On the firſt removal of the dreſſings, and after taking away the iron, which cou'd only be done with difficulty, ſo deeply had it ſtuck, it was with pleaſure and aſtoniſhment that the ſight was found to return immediately, even before the eye had been replaced. The inflammation which followed was ſoon appeaſed by proper remedies, and viſion was re-eſtabliſhed in its original perfection.

Mr. White makes mention of an analogous example in his book of ſurgical caſes, with this difference, however, that the eye was protruded in a ſtill greater degree.

Theſe two inſtances confirm the one recorded by Covillard, and weigh againſt what Maitre Jean has ſtated, namely, that Covillard's caſe is not authentic.

In order to conceive the truth of the foregoing obſervations, we have only to recollect the way in which the [illegible] is retained in, and connected with the orbit. The ſurface of the boundaries of each orbit (ſays M. Louis, in defending Covillard's caſe,) is oblique, and inclines behind more towards the temple than the noſe. The eye-ball is fixed on the ſide towards the noſe, and juts out in front beyond the cavity of the orbit. Hence, it is manifeſt from the ſlighteſt examination, that the globe of the eye, in the natural ſtate, is partly ſituated on the outſide of the orbit. When it is alſo conſidered that the optic nerve is very looſe, in order to be adapted for readily following, without being at all ſtretched, all the rotatory motions of the eye-ball, produced by the action of the different muſcles belonging to this organ, we can then have no difficulty in imagining how the eye may make an immenſe protruſion outward, in conſequence of an inconſiderable ſwelling, and how it may ſeem to be quite diſplaced from its ſocket, without either the optic nerve or the muſcles being torn or lacerated.

EXORCISM, Εξορκισμος, prayers or conjurations wherewith to exorciſe, *i. e.* to drive out devils or dæmons from perſons apprehended to be poſſeſſed, or to preſerve from danger.

The word is derived from the Greek, εξορκιζειν, *adjurare*, *conjurare*, *to adjure*, or *conjure*. In moſt dictionaries, exorciſm and conjuration are uſed as ſynonymous; but in reality, conjuration is only a part of the exorciſm; and the exorciſm the ceremony entire. The conjuration is properly the formula, where the devil is commanded to come forth, &c.

Exorciſms are of great uſe in the Romiſh church; their prelates, &c. are frequently exorciſing dæmoniacal perſons. The prieſts make holy water by exorciſing common water a certain number of times. In reality, the exorciſm is a part in moſt of their conſecrations.

Exorciſms had anciently another and farther purpoſe; being applied by way of trial or purgation to extort the truth from the accuſed.

The exorciſm, in this ſenſe, was a ſort of bread conjured and exorciſed for the purpoſe; and the opinion was, that if the perſon was criminal he could not ſwallow the bread.

This, it ſeems, was a frequent practice in the time of our Edward III. and the bread thus exorciſed was ſaid to be corſned.

Linderbroeck gives inſtances of exorciſms with barley-bread, and others with cheeſe; and hence, probably, might ariſe that popular imprecation, "May this bread choak me, if I tell a lye." See Ordeal and Judicium *Dei*.

EXORCIST, in the *Romiſh Church*, a prieſt, or tonſured clerk, who has received the four leſſer orders, one of which is that of exorciſt.

The term is likewiſe applied to a prelate, or to a prieſt delegated by a prelate, who actually exorciſes a perſon poſſeſſed.

It is a diſpute among divines whether ever the Greeks had any ſuch order as that of exorciſt. Fa. Goar, in his Notes on the Greek Euchologion, has made it probable they had, from ſeveral concurring paſſages in St. Dionyſius and St. Ignatius Martyr.

The ordination of exorciſts is performed in the time of maſs, their principal office being to expel devils. The fourth council of Carthage, can. 7. appoints, that in the ordination of exorciſts, the biſhop, putting the book of exorciſms

orciſms in their hands, ſhall ſay theſe words: "Receive it, and keep it in remembrance, and have power to lay hands on energumeni, whether baptiſed or catechumens; which form ſtill obtains."

M. Fleury mentions certain people among the Jews who travelled round the country, making profeſſion of driving out devils by invocations, which, they pretended, had been taught them by Solomon; theſe were alſo called exorciſts. See Joſeph. Antiq. Jud. lib. viii. cap. Origen. Tract. xxxv. in Matt. 35. 63.

EXORDIUM, in *Oratory*, the preamble or beginning of a diſcourſe or ſpeech, ſerving to prepare the audience and introduce the matter in hand.

The word is formed from the Latin *ordiri, to begin*, by a metaphor taken from the weavers, who are ſaid, *ordiri telam, to begin*, or *warp* a web, by diſpoſing and ordering the threads in a certain manner for the future work. See Warp.

The exordium, on other occaſions, is called the *prologue*, *prælude*, and *proem*.

Cicero defines exordium a part of an oration, whereby the minds of the audience are duly prepared for what remains to be ſaid. The exordium is a part of principal importance, and is to be laboured with extraordinary care; whence Tully calls it "difficillima pars orationis."

Cicero and Quinctilian mention three ends, to one or other of which it ſhould be ſubſervient; *viz.* "reddere auditores benevolos, attentos, dociles." The firſt end, or that of conciliating the good will of the hearers, may be effected by a ſelection of topics, in cauſes at the bar, from the particular ſituation of the ſpeaker himſelf, or of his client, or from the character and behaviour of his antagoniſt contraſted with his own; on other occaſions, from the nature of the ſubject, as cloſely connected with the intereſt of the hearers; and, in general, from the modeſty and good intention with which the ſpeaker enters upon his ſubject. The ſecond end, or that of exciting and engaging the attention of the hearers, may be accompliſhed by giving them ſome hints of the importance, dignity, or novelty of the ſubject; or ſome favourable view of the clearneſs and preciſion with which it is to be treated, and of the brevity with which it is to be diſcuſſed. In order to effect the third end, or to render the hearers docile, or open to perſuaſion, the ſpeaker muſt begin with ſtudying to remove any particular prepoſſeſſions they may have contracted againſt the cauſe, or ſide of the argument which he eſpouſes.

The ancient critics diſtinguiſh two kinds of introduction, which they call "Principium," in which the orator plainly and directly profeſſes his aim in ſpeaking: and "Inſinuatio," where, preſuming the diſpoſition of the audience to be much againſt the orator, he muſt gradually reconcile them to hearing him, before he plainly diſcovers the point which he has in view. Of this latter ſort of introduction we have an admirable ſpecimen in Cicero's ſecond oration againſt Rullus.

Exordiums are of two kinds; either juſt and formal, or vehement and abrupt. In the firſt, the audience is prepared and conducted by due and eaſy ſteps; in the ſecond, the orator, as if ſeized with ſome ſudden paſſion, breaks out upon his audience at once. Such is that exordium of Iſaiah; "Hear, Oh heavens! and give ear, Oh earth!" Or that of Cicero againſt Catiline; "Quouſque tandem abutere patientia noſtra, Catilina?" Abrupt exordiums are moſt ſuitable on occaſions of extraordinary joy, indignation, or the like; though we have inſtances of panegyrics of the greateſt orators, begun abruptly, without any ſuch occaſions. Such is that of Gorgias, who began his eloge of the city and people of Elis with Ηλις, πολις ευδαιμων, *Elis, beata civitas.* Abrupt, haſty, exordiums, were more to the taſte and manner of the Greeks than of the Latins.

Agreeably to the objects which the orator ſhould have in view in this part of his diſcourſe, as we have already ſtated them, the requiſites in an exordium are, 1. *Propriety*, whereby the exordium appears eaſy and natural, becomes of a piece with the whole diſcourſe, and matches it as a part does the whole; ſo that it could not be accommodated to any other, or, perhaps, a contrary occaſion. The ancient orators were very defective in this point; their exordiums had frequently nothing in common with the ſubject.

In order to render introductions natural and eaſy, Dr. Blair ſuggeſts that they ſhould not be planned, till the ſubſtance of the diſcourſe has been thoroughly digeſted in the mind. This mode of forming an introduction is conformable to the rule given by Cicero, though not always to his practice. "Omnibus rebus conſideratis," ſays he, "tum denique id quod primum eſt dicendum, poſtremum ſoleo cogitare, quo utor exordio. Nam ſi quando id primum invenire volui nullum mihi occurrit, niſi aut exile, aut nugatorium, aut vulgare;" *i. e.* "when I have planned and digeſted all the materials of my diſcourſe, it is my cuſtom to think, in the laſt place, of the introduction with which I am to begin. For if at any time I have endeavoured to invent an introduction firſt, nothing has ever occurred to me for that purpoſe, but what was trifling, nugatory, and vulgar."

2. *Modeſty*, or an ingenuous baſhfulneſs, which recommends the orator exceedingly to the favour of his audience. This is what Cicero extols ſo much in L. Craſſus, "Fuit enim in L. Craſſo pudor quidnam, qui non modo non obeſſet ejus orationi, ſed etiam probitatis commendatione prodeſſet." The ſame Tully owns of himſelf, that at the beginning of his oration every limb trembled, and his whole mind was in a flutter. The vain-glory of that author ſhould be carefully avoided, of whom Horace ſpeaks, and who began his poem "Fortunam Priami cantabo et nobile bellum."

The modeſty of the orator ſhould diſcover itſelf not only in his expreſſions at the beginning, but in his whole manner; in his looks, in his geſtures, and in the tone of his voice. However, the modeſty of an introduction ſhould never betray any thing mean or abject. The orator, whilſt he exhibits to his hearers modeſty and diffidence, real and not affected, ſhould manifeſt a becoming ſenſe of dignity, ariſing from a perſuaſion of the juſtice or importance of the ſubject of which he is to ſpeak. The modeſty of an introduction requires that it ſhould not promiſe too much. "Non fumum ex fulgore, ſed ex fumo dare lucem." Horace.

"He does not laviſh at a blaze his fire.
Sudden to glare, and then in ſmoke expire;
But riſes from a cloud of ſmoke to light,
And pours his ſpecious miracles to ſight."—Francis.

Although, in general, the orator ſhould not put forth his whole ſtrength in the beginning, but gradually riſe as his diſcourſe advances; yet there are caſes in which he may be allowed to ſet out in a high and bold tone; *e. g.* when he riſes to defend ſome cauſe which has been much decried by the public. In ſubjects too of a declamatory nature, and in ſermons, where the ſubject is ſtriking, a magnificent introduction has ſometimes a good effect, if it be properly ſupported in the ſequel. Boſſuet, Flechier, and the other celebrated French preachers, very often begin their diſcourſes with laboured and ſublime introductions; theſe raiſe attention, and throw a luſtre on the ſubject; but every ſpeaker ſhould be on his guard againſt ſtriking a higher note at the beginning than he is able to keep up in his progreſs, and thus diſappointing the expectations which he has excited. Among Engliſh preachers, attempts of this kind are not always ſo ſucceſsful. Variety ſhould be ſtudied in introductions as much as poſſible. Explanatory introductions from the context are the moſt ſimple of any, and frequently the beſt that can be uſed ; but they ſhould never be long. An hiſtorical introduction has generally a happy effect in rouſing attention ; when one can lay hold upon ſome noted fact that is connected with the text or diſcourſe, and by a proper illuſtration of it, open the way to the ſubject that is to be treated of.

3. *Brevity*, not amplified or ſwelled with a detail of circumſtances, or a long circuit of words ; and in this reſpect it ſhould be accommodated to the length of the diſcourſe ; nor ſhould the introduction anticipate any material part of the ſubject.

4. The *ſtyle* of the exordium ſhould be juſt, eaſy, and pleaſant. Quinctilian facetiouſly compares a faulty exordium to a ſcarred face, which is preſently diſcerned, and very diſagreeable. Thus, Cicero, " Veſtibula, adituſque ad cauſam facias illuſtres."

Correctneſs of expreſſion is peculiarly requiſite on account of the ſituation of the hearers, who are then more diſpoſed to criticize than in any other ſtage of the oration or diſcourſe; becauſe they are as yet unoccupied with the ſubject or the arguments, and their attention is chiefly, if not wholly, directed to the ſpeaker's ſtyle and manner. A correct plainneſs, an elegant ſimplicity, is the proper character of an introduction, ; " ut videamur," ſays Quinctilian, " accuraté non callidé dicere."

5. *Calmneſs* of manner is peculiarly ſuitable to the exordium. This is ſeldom the place for vehemence and paſſion. Emotions muſt riſe as the diſcourſe advances. The minds of the hearers muſt be prepared, before the ſpeaker can venture on ſtrong and paſſionate ſentiments. To this rule there are ſome exceptions, as, for inſtance, when the ſubject is ſuch that the mere mention of it naturally awakens ſome paſſionate emotion, or when the unexpected preſence of ſome perſon or object, in a popular aſſembly, inflames the ſpeaker, and makes him break forth with unuſual warmth. Either of theſe will juſtify what is called the exordium *ab abrupto*. An inſtance of this kind we have already referred to in Cicero's firſt oration againſt Catilinè. However, introductions of this kind ſhould rarely occur. In the introduction the ſpeaker ſhould prepare the way for thoſe warm emotions, which he deſigns to raiſe in the ſubſequent parts of his diſcourſe.

The exordium appears an eſſential part of an oration ; though anciently in the Areopagus, Julius Pollux tells us they ſpoke without any exordium, and paſſions, and any peroration or epilogue. The like is ſaid to have been done by Xenophon, who began thus : " Darius et Pariſatis duos habuere filios."

EXORMISTOS, in *Ichthyology*, a name given by ſome of the old writers to that ſpecies of the petromyzon which other authors call the lampetra fluviatilis, and we in Engliſh the lampern. This is diſtinguiſhed by Artedi by the name of the petromyzon, with only one ſeries of ſmall teeth in the verge of the mouth, and ſome large ones, below. See Mustela, Lampetra, and Petromyzon.

EXOS, the name by which Rondeletius diſtinguiſhes the acipenſer huſo. See Sturgeon.

EXOSTOSIS, from εξ, *out of*, and οστεον, *a bone*. This term, in *Surgery*, ſignifies an oſſeous tumour growing on a bone. Alſo, a ſwelling of the bone itſelf.

Boyer remarks, that a ſwelling may take place in bones as well as other parts of the body. The particular kind of tumour which occaſionally forms on the ſurface of the bones, is that to which this writer aſſigns the appellation of *exoſtoſis*. He notices, however, that this name comprehends different ſpecies, which ſhould be conſidered in a diſtinct manner. Thus, *oſteo-ſarcoma* is one peculiar affection ; and there is another ſpecies of exoſteſis, different from all others, and which conſiſts principally in a thickening of the perioſteum. Boyer is of opinion, that the diſeaſe might be very properly named *perioſtoſis*.

In caſes of exoſtoſis, the bony ſwelling acquires, on ſome occaſions, ſuch a degree of hardneſs, that no veſtiges of a fibrous texture can be diſcerned, and it abſolutely reſembles ivory. In ſome inſtances, the ſtructure of the tumour is ſpongy ; and in others the ſwelling is compoſed of a maſs of fleſhy and bony matter blended together.

According to Boyer, the bones moſt frequently affected with exoſtoſis are the broad bones of the head, the lower jaw, ſternum, humerus, radius, cubitus, the bones of the carpus, and the femur, and tibia. However, he remarks, that there is bone, which may not become the ſeat of the diſeaſe, and the affection may extend to a ſmall, or a conſiderable portion of it. It is not uncommon to find the bones of the cranium affected with exoſtoſis over their whole extent ; and Boyer inſtances the oſſa parietalia, as ſometimes acquiring an inch in thickneſs, in conſequence of the affection.

In the majority of caſes, an exoſtoſis riſes from the ſurface of a bone, and appears in the form of a hard round tumour. It ſometimes occurs near the extremities of the long bones, and, at other times, near the middle portion. It is remarked, that exoſtoſes, originating from a venereal cauſe, and commonly called *nodes*, are found, for the moſt part, on compact bones, and ſuch of theſe as are not thickly covered with ſoft parts, as, for inſtance, the bones of the cranium and face, the internal ſide of the tibia, &c.

Mr. John Bell has treated of tumours of the bones in the third volume of his Principles of Surgery. The following extract will ſerve to ſhew ſome of this gentleman's opinions upon the ſubject : " Many things conſpire (ſays this author) to give the tumour proceeding from a bone a peculiar aſpect ; it is always irregular and anomalous, never ſimple. I have rarely ſeen a ſingle bony protuberance ariſing from the head, or ſhaft, of a ſingle bone. When a bone falls into diſeaſe, a large proportion of tendinous and muſcular parts of burſæ, and of cellular ſubſtance partake of the morbid action. The bone lies in the centre of the limb, connected by its larger head with a joint, and by its perioſteum with the tendons, burſæ, and muſcles ; and all this maſs of parts is, ſooner or later, affected ; and ſince every depoſition from veſſels appointed for the ſecretions of bone is ſolid, and every increaſe of ſuch a tumour permanent, it ſoon atttains a great ſize ; it is ponderous and maſſive from the proportion of bony ſecretion, and from the various ſtructure of theſe ſeveral parts, it has every irregularity of form and ſubſtance.

" When the tumour of a bone has attained a conſiderable ſize, much of the original ſtructure is deſtroyed, and a new irregular maſs of gelatinous and bony matter is ſubſtituted for it. The bony tumour is firm, bulky, and ponderous, but not ſolid ; feeling it from without, we can conjecture of what ſubſtance it is compoſed within ; we are ſenſible that the tumour is covered by a ſhell, bony in moſt parts of its circumference, cartilaginous in ſome parts, and, throughout the whole, yielding and elaſtic ; we are ſenſible, alſo, that within there are irregular points, or ſpiculæ traverſing the cavities, or cells, of the hollow tumour ; that theſe are mixed with the cartilaginous ſubſtance, and with irregular collections of matter, partly purulent, but chiefly gelatinous; we are ſenſible of ſuch ſoft cartilaginous and gelatinous parts being ſucceſſively added, in the progreſs of its growth to the tumour, which was, at the firſt, ſolid and firm; and we find at laſt, by pain and partial ulcerations, and by the increaſe of fluctuation and redneſs at particular points, that ulceration, the laſt ſtage of the diſeaſe, approaches. Then the limb is effectually ruined, and the patient muſt ſubmit to amputation, or die of hectic.

"When ſuch tumour is diſſected, we find our ſuſpicions of its internal ſtructure confirmed; we ſee that foul matter flow out, when we open into the centre of the tumour, which we felt but indiſtinctly through its walls; the parts which appeared the moſt ſolid are hollowed out by ulceration, and full of foul and putrid ſanies; while the bone has been declining into diſeaſe, the cancelli and marrow have been degenerating into a ſort of fatty maſs, with which much of the cavity of the tumour is filled, and thence ſuch diſeaſe has been very generally deſcribed under the name of *oſteo-ſteatoma*. This fatty excretion, occupying the diſeaſed cavity, is the part which, when the tumour burſts into an open ulcer, throws out ſuch prolific fungus, growing apparently from the ſubſtance of the bone, and ſprouting up, when amputated, in the courſe of a few hours. The ſolid bone, whether radius, or thigh-bone, is annihilated, and a mere ſhell of oſſeous matter ſubſtituted in its place, and that in a manner ſo peculiar, that it muſt ſeem to the unintelligent obſerver as if the ſmall and ſolid bone had been expanded into an extenſive and flat plate of oſſeous ſubſtance, whereas the proceſs is in truth very ſimple and very intelligible. The bone dies piecemeal of ulceration, what, in technical language, is termed caries, and is conveyed away by abſorption; but the bone being dead, the ſurrounding membranes, *viz.* the perioſteum and tendinous expanſions, which once formed a part of its ſyſtem of circulation, continue ſtill alive and ready to ſecrete new bone; and thus it happens, that while a carious abſceſs preſerves a large cavity full of foul matter, the ſurrounding membranes continue ſecreting bone, which, like a ſhell, thin and expanded, covers this cavity, and forms the walls of the tumour, of which ſome part is compoſed of thin expanded bone, reſembling a cranium, ſome of cartilage, ſome of thickened membrane; and this ſhell is formed in proportion as the original fabric of the bone is deſtroyed.

"Bone is deſtroyed by this internal ulceration, juſt as it is by open caries, piecemeal; the proceſs would not be ulceration, if, while one part were periſhing, the other were not active and ſecreting new matter; ſo vigorous ſtill is the general life of the bone, while the internal parts are thus ſuffering, that while one ſide is waſting with ulcer, the other ſide is often ſecreting bone irregularly and profuſely, and ſhooting out into fantaſtic forms among the membranes and ſurrounding ſoft parts, whence the centre of the tumour is cavernous and cellular, and the walls often rough with ſpinous and projecting points. So merely local is the action of arteries in a tumour, whether oſſeous or ſoft, that one ſide, or part, or bump of a tumour, grows viſibly and protrudes; the features and external form of the tumour gradually changing, without any ſenſible cauſe; and ſo peculiar is the ſecretion of each ſpecies of vaſcular ſtructure, according to the original deſtination of the part, that in one part of the tumour is generated bone, in another griſtle, in another gelatinous effuſion; while in another part, the vaſcular action is violent and deſtructive, and the ſolid bone, marrow, and ſurrounding membranes, are all reſolved into a foul and fetid ſuppuration. From the perioſteum is ſecreted bone: from the marrow, this ſteatomatous and ſolid fat, with which much of the tumour is filled; to the tendinous and aponeurotic parts we can diſtinctly trace the cartilaginous ſecretion; and the gelatinous effuſions, we can perceive, even during life, have their walls thicker, or thinner, according to the degree of inflammation.

"Theſe are the external characters and internal conditions of a tumour occupying any of the bones. Such tumour ariſes often from a bruiſe, or fracture; ſometimes from a leſs obvious cauſe, or from internal diſeaſe. The radius, for example, is fractured at the wriſt, re-unites and heals; but heals clumſily, the thickening never ſubſides, the pain never ceaſes, and, though not great, is greater than what is natural to a fracture. At length, a ſenſible tumour ariſes; at firſt it is firm, but in proportion as it increaſes in ſize, it becomes ſomewhat ſoft and elaſtic, the thin plate of bone, of which it is compoſed, yielding to the diſtention from within. From time to time the tumour changes its form, ſtill increaſing in bulk. On the ſide of the radius, it is firm and ſolid; it bends and yields at the parts moſt diſtant from it; it is plainly bony at its baſis, and as obviouſly cartilaginous in the extreme part of its circle; it plainly contains matter in thoſe ſofter parts, where it yields to the impreſſion of the finger. Cartilaginous knobs ariſe, and ſometimes are reddened on the ſurface; and, at certain points, the fluctuation is of ſuch a kind, as to imply that the effuſion is in part of a gelatinous nature. Thus the tumour grows and extends, with various irregularities in form and conſiſtence; it overhangs the dwindled hand, the uſe of the joint is loſt, and the patient, who might gladly have been delivered of it at an earlier period, has, in the end, no choice left; for, when once it burſts into carious ulceration, it never heals, the fetor is inconceivably overcoming, attended with hectic. You are alſo to remark, that, when ſuch diſeaſe takes place in the hand itſelf, the joints of each of the fingers grow out into tumours, at firſt of a heart-like form, correſponding with the articulations of the finger bones; but, in proceſs of time, they grow to globular, irregular, and almoſt tranſparent tumours, ſtill firm, or, at leaſt, of a cartilaginous firmneſs. The whole hand degenerates into a deformed maſs, diſcoloured, ulcerated, and fetid; from the individual knobs of which deformed maſs, the points of the reſpective fingers project like griffin's claws, with crooked nails of enormous length." Page 58—60.

The foregoing paſſage makes us tolerably well acquainted with Mr. John Bell's ſentiments relative to the pathology of exoſtoſes, and though we do not ourſelves adopt ſome of his concluſions, nor think that all bony tumours coincide with his account, yet many caſes certainly anſwer the deſcription which he has given.

Some exoſtoſes cannot be diſcovered before the patient's death. Such was the caſe referred to by Boyer, of a perſon whoſe parietal bone was found after death to be three times thicker than natural. A ſimilar caſe is alſo related in the memoirs of the academy of Dijon. In the latter example, the patient died from an exoſtoſis on the internal ſide of the os pubis. The tumour, by preſſing on the neck of the bladder, prevented the paſſage of the urine, and the introduction of the catheter.

Boyer notices the poſſibility of miſtaking the head of a luxated bone for an exoſtoſis. He informs us, that this happened with a young man, whoſe clavicle was diſlocated at the end, which is articulated with the ſternum. The tumour, formed by the end of the diſplaced bone, was miſtaken for an exoſtoſis, and was treated as ſuch, of courſe, with no benefit.

Boyer alſo adverts to the liability of miſtaking the enlargements of the ends of ricketty bones for exoſtoſes. Fungous excreſcences of the dura mater might likewiſe (as the ſame author explains) be erroneouſly conceived to be exoſtoſes; for, after they have deſtroyed a part of the bones of the cranium, they form an external protruſion. Their real nature, however, may be eaſily diſcriminated by attending to their conſiſtence and progreſs, and particularly their pulſatory motion, which correſponds with the action of the arteries in general. We need not here ſay more concerning theſe ſwellings, as they are already deſcribed in another part of this Cyclopædia. See Dura Mater, *Tumours of*.

There are certain ſymptoms which may be ſaid to be common to all exoſtoſes; ſuch are, a ſwelling; a ſenſe of weight; pain, or at leaſt a degree of uneaſineſs ariſing from the morbid action; and deformity.

Another claſs of ſymptoms may be called *particular*, becauſe they are entirely dependent on the ſituation of the tumour. Thus, as Boyer obſerves, and as we have related in the article Exophthalmia, if an exoſtoſis were to take place in the orbit, the eye would neceſſarily be expelled from that cavity. An exoſtoſis ariſing from the inner ſurface of the clavicle, or ſternum, might occaſion preſſure of conſiderable blood-veſſels, and on the thoracic viſcera, ſo as to induce a train of very dangerous and even fatal conſequences

An exoſtoſis, ariſing from the internal ſide of the os pubis, may give riſe to a fatal retention of urine, as, indeed, we have already detailed. A ſimilar tumour, ſimilarly ſituated, might alſo render parturition, in the natural way, impoſſible.

The generality of ſurgical writers repreſent ſcrofula as being a cauſe of exoſtoſes. This ſtatement, however, ſeems to reſt on no foundation whatever. The ſwelling of the joints, when they are affected with ſcrofulous diſeaſe, is not produced by an expanſion of the bones themſelves, but altogether by a thickening of the ſoft parts, ſometimes conjoined with a collection of a fluid reſembling glair, or of purulent matter in the capſular ligament. The head of a bone, really enlarged from ſcrofula, has never yet been demonſtrated, and cannot be found in any of the collections of morbid preparations in the various muſeums. The particular form of diſeaſe, with which ſcrofula affects the bones, we ſhall deſcribe in ſpeaking of the *White Swelling*.

A ſcorbutic diatheſis is alſo ſet down by authors as ſometimes exciting the growth of exoſtoſes: on this point, we can only profeſs our ignorance of any rational evidence in favour of the opinion.

The venereal diſeaſe does undoubtedly occaſion one ſort of exoſtoſes, denominated *nodes*; but, theſe we ſhall diſmiſs from preſent conſideration.

It is painful for us to be obliged to acknowledge, that we are almoſt in total ignorance, in regard to the cauſes of exoſtoſes; for, excepting contuſions and fractures, which ſometimes unqueſtionably lead to the production of bony tumours, we have no certain knowledge of any others.

Mr. John Bell informs us, that he has ſeen a woman's ankle fall into this diſeaſe, in conſequence of a very trivial accident; the tibia and fibula grew into a common tumour, the bones ſeemed annihilated, and a large oſſeous ſhell appeared to be ſubſtituted in their place. In the courſe of the diſeaſe, the leg became twiſted round in a ſingular manner, and enlarged to the ſize of a pillow of a ſettee. The woman died of hectic from the open caries of the tumour. The ſame author remarks, that the wriſt, which is more expoſed to ſprains and fractures, is moſt liable to be thus deformed and ruined. He repreſents the hand itſelf as being alſo particularly ſubject to ſimilar diſorder. The original injury is ſome ſlight blow, or ſprain; one finger is firſt deformed; joint after joint enlarges; one finger after another becomes crooked; the nails project like talons, and force their way into the very fleſh of the ſwelled and ulcerated hand, which, according to Mr. John Bell, they ſometimes penetrate through and through. At length, the hand degenerates into an unwieldy and irregular maſs, ſtudded with knobs and bony tumours. This ſurgeon tells us, alſo, that in conſequence of a neglected fracture of the collar-bone, in a ſtout young man, he once ſaw a tumour produced; partly conſiſting of bone, and partly of cartilage, riſing to the height of ſix inches, of round figure, and inſulated, moving when the arm was moved, too large and too critically ſituated over the axillary artery, to admit of extirpation, and which Mr. John Bell doubts not has by this time become carious, and occaſioned death.

When exoſtoſes originate from external violence, the exciting cauſe is involved in no obſcurity; but the cauſes in moſt other inſtances ſeem to baffle all human reſearch. Frequently, a conſtitutional diſpoſition to the formation of bony tumours, in various parts of the body, ſeems to prevail. Mr. Samuel Cooper, in his "Dictionary of Practical Surgery," quotes an example of a boy, who came out of Cornwall, ſo exceſſively afflicted with an apparent propenſity to exoſtoſes, or an exuberant depoſition of bony matter, that a very trifling blow would occaſion a bony ſwelling on any bone of his body. The ligamentum nuchæ was oſſified, and prevented the motion of his neck; the margins of the axillæ were alſo converted into bone, ſo that the poor lad was, as it were, completely pinioned.

There is one ſpecies of exoſtoſis remaining to be noticed, which is of a very peculiar kind, as it is in its appearance exceedingly like a bony fungus.

A ſtriking inſtance of ſuch a diſeaſe has been recorded by Mr. Abernethy. The caſe being highly intereſting, we ſhall take the liberty of quoting it. The patient, who was 34 years of age when the account was written, perceived, when about ten years old, a ſmall tumour on his left cheek, which gradually attained the ſize of a walnut, and then remained for ſome time ſtationary. About a year afterwards, the tumour having again enlarged, a cauſtic was applied to the integuments, ſo as to expoſe the bone. The actual cautery was next applied, and an opening thus made into the antrum. After the exfoliation, the antrum became filled with a fungus, which roſe out upon the cheek, and could not be reſtrained by any applications. Part of the fungus alſo made its way into the mouth, through the ſocket of the ſecond tricuſpid tooth, the other teeth remaining natural. The diſeaſe continued in this ſtate nine years, occaſionally bleeding in an alarming way. When the patient was in his 20th year, the whole fungus ſloughed away during a fever, and did not return. After this, the ſides of the aperture in the bone began to grow outwards, forming an exoſtoſis, which grew to a great magnitude. A ſmall exoſtoſis took place in the mouth, but became no larger than a horſe-bean. The exoſtoſis of the maxillary bone was of an irregular figure, and projected from the whole circumference of the aperture a great way directly forward. Mr. Abernethy compares its appearance, when he was writing, with that of a large tea-cup faſtened upon the face, the bottom of which may be ſuppoſed to communicate with the antrum. The diameter of the cup, formed by the circular edge of the bone, was three inches and a half: the depth two inches and ſeven-eighths. The general height of the ſides of the exoſtoſis, from the baſis of the face, was two inches; its walls were not thick, and terminated in a thin circular edge. The integuments,

teguments, as they approached this edge, became extenuated, and they extended over the edge into the cavity. The exoſtoſis reached to the noſe in front, and to the maſſeter muſcle behind; above it included the very ridge of the orbit, and below it grew from the edge of the alveolary proceſs. A line that would have ſeparated the diſeaſed from the ſound bone, would have included the orbit and noſe, and indeed one half of the face. Mr. Abernethy ſaw no means of affording the man relief. Med. Chirg. Tranſ. vol. 2.

In regard to the treatment of exoſtoſes, it is exceedingly difficult to lay down any determinate rules. With the exception of venereal nodes, we cannot ſay that we are acquainted with any remedy which has the power of diminiſhing bony tumours. Perhaps bliſters kept for a long while open, by means of the ſavin cerate, and applied to the neareſt ſurface of the integuments, might have the effect of exciting the action of the abſorbents, ſo that the depoſited bony matter would be at leaſt in part removed. That bliſters would operate in this manner, we may conclude from their having been known to diminiſh the ſwelling of venereal nodes, after mercury has ceaſed to be productive of any benefit. However, we do not mean to repreſent this plan as likely to anſwer fully in practice; for, even were it to prove ſucceſsful, it could only be after ſuch time and perſeverance as few patients would allot.

The chief method of getting rid of an exoſtoſis is by attacking the tumour with a cutting inſtrument, and it is obvious that this mode of proceeding cannot be adopted, except when no anatomical conſiderations forbid it. Hopes of its ſucceſs, alſo, ſhould never be ſanguine; becauſe, though you may ſucceed in removing every particle of the bony ſwelling, ſtill the depoſition of bone may continue, and the diſeaſe recur, and this even in a more malignant form.

When an exoſtoſis has acquired much magnitude, it ſeldom admits of being cut, or ſawn away. But there are exceptions to this remark; for Heiſter records an example of an exoſtoſis, ſituated on the middle of the ſternum, and as large as a child's head, being ſucceſsfully extirpated. If an exoſtoſis were to be met with, growing on the middle part of one of the long cylindrical bones, with rather a narrow baſe, an attempt might be prudently made to remove the tumour, notwithſtanding its ſize might be very great. When the attachment of the ſwelling is on the head of a bone, near a large joint, an endeavour to extirpate the diſeaſe is much more dangerous.

It would be in vain to pretend to detail particularly how the operator is to conduct himſelf in extirpating exoſtoſes. His firſt object ſhould be, if poſſible, to make ſuch inciſions through the ſoft parts as will expoſe the baſe of the tumour, ſo as to allow the ſaw to be applied to it. When this can be effected, it is manifeſt that the whole of the ſwelling may be removed by one ſection made with the ſaw. In the majority of caſes, ſmall ſhort ſaws with long handles, in a word, the inſtruments deſcribed in Mr. Hey's "Practical Obſervations in Surgery," will be found much more proper and convenient than larger ones.

Sometimes, when owing to depth of ſituation, or ſome other anatomical reaſon, no direct attempt to cut through the baſe of an exoſtoſis can be made, the ſurgeon may venture to remove the tumour by attacking its ſurface with trephines, the ſaws deſcribed by Hey, or with a gouge and mallet, as the French ſurgeons are ſo much in the habit of doing. When the conſiſtence of the exoſtoſis is not too hard, a ſtrong knife may be occaſionally employed for removing portions of the ſwelling, which purpoſe it will accompliſh better than any ſaw.

The ancients, indeed, we might ſay ſeveral of the moderns, have attempted to deſtroy exoſtoſes with the actual and potential cautery. Sometimes theſe violent means have fulfilled the object in view; but, frequently, inſtead of affording relief, they have killed a large portion of the bone, and converted the diſeaſe into the more afflicting one of necroſis, attended with large ſores and abſceſſes, and often with ſuch debility and hectical ſymptoms, as have ended in death.

Few good practitioners of the preſent day, in England, ever have recourſe to this plan for the extirpation of exoſtoſes.

When prudence prohibits an endeavour to cut away an exoſtoſis, the diſeaſe ſhould never be ſuffered to expand itſelf in ſo great a degree as to deprive the patient of the choice of parting with his limb for the preſervation of his life. Amputation ſhould always be performed ere the diſorder attains this deplorable ſtate.

We ſhall conclude the preſent article with this general obſervation, that if an attempt is to be made to extirpate an exoſtoſis, let it be done at an early period of the diſeaſe, before its ſize is very conſiderable.

EXOSTRA, in the *Ancient Theatre*, a place where ſuch parts of the play were recited as were ſuppoſed to be acted privately in the houſe.

Exostra was likewiſe the name of a warlike engine uſed in the ſieges of towns.

EXOTERIC and Esoteric, are terms denoting *external* and *internal*, and applied to the double doctrine of the ancient philoſophers: the one was public or exoteric, the other ſecret, acroamatic, or eſoteric. The firſt was that which they openly profeſſed and taught to the world; the latter was confined to a ſmall number of choſen diſciples. This method was derived originally from the Egyptians, who, according to the united teſtimony of Herodotus, Diodorus Siculus, Strabo, Plutarch, &c. had a two-fold philoſophy, one ſecret and ſacred, another public and common. The ſame practice alſo obtained among the Perſian Magi, the Druids of the Gauls, and the Brachmans of India. The Egyptian prieſts, with whom it originated, ſuſtained the character of judges and magiſtrates, and probably introduced this diſtinction with a view to the public welfare, and to ſerve the purpoſes of legiſlation and government. Clement of Alexandria informs us, that they communicated their myſteries principally to thoſe who were concerned in the adminiſtration of the ſtate; and Plutarch confirms the ſame declaration. However, others have ſuppoſed that they invented the fables of their gods and heroes, and the other external ceremonies of their religion, to diſguiſe and conceal natural and moral truths; but whatever was the motive of their practice, it was certainly applied to political purpoſes. See Aristotle.

EXOTIC, Εξωτικος, a term properly ſignifying *foreign*, or *extraneous*, *i. e.* brought from a remote or ſtrange country. In which ſenſe we ſometimes ſay, *exotic*, or *barbarous terms* or *words*, &c.

The word is derived from the Greek, εξω, εξωθεν, *extra*, *without*, *on the outſide*.

Exotic is chiefly applied to plants which are natives of foreign countries, particularly thoſe brought from the Eaſt and Weſt Indies, and which do not naturally grow in Europe.

The generality of exotics, or exotic plants, do not thrive in England without ſome peculiar care and culture; they require the warmth of their own climates, whence the uſe of hot-beds, glaſs-frames, green-houſes, &c. See Green-*houſe* and Stove.

In ſending plants from one country to another, particular cautions are neceſſary. The plants ſent from a hotter country to a colder, ſhould be always put on board in the ſpring of the year, that the heat of the ſeaſon may be advancing as they approach the colder climates; and on the contrary, thoſe which are ſent from a colder country to a hotter, ſhould be ſent in the beginning of winter.

The beſt way of packing up plants for a voyage, if they be ſuch as will not bear keeping out of the earth, is to have boxes with handles, filling them with earth, and planting the roots as cloſe together as may be; the plants ſhould be ſet in theſe boxes three weeks before they are to be put on board; and in good weather they ſhould be ſet upon the deck, and in bad removed, or covered with a tarpaulin.

If they are going from a hotter country to a cold one, they muſt have very little moiſture; if, on the contrary, they are going from a colder to a warmer, they may be allowed water more largely, and being ſhaded from the heat of the ſun, they will come ſafe.

Many plants, however, will live out of the earth a great while; as the ſedums, euphorbiums, ficoides, and other ſucculent ones. Theſe need no other care than the packing of them up with moſs in a cloſe box, and there ſhould be a little hay put between them, to prevent them from wounding or bruiſing one another, and holes bored in the boxes to keep them from heating and putrefying. In this manner they will come ſafe from a voyage of two or three, or even four or five months.

Several trees alſo will come ſafely in the ſame manner, taking them up at a ſeaſon when they have done growing, and packing them up with moſs. Of this ſort are oranges, olives, capers, jaſmines, and pomegranate-trees. Theſe, and many others, are annually brought over thus from Italy; and though they are three or four months in the paſſage, ſeldom miſcarry. And the beſt way of ſending over ſeeds is in their natural huſks, in a bag, or packed up in a gourd-ſhell, keeping them dry, and out of the way of vermin. Miller.

Dr. Liſter has a diſcourſe in the Philoſoph. Tranſ. on Exotic Diſeaſes, *i.e.* ſuch diſeaſes as are never bred among us, but brought, from time to time, by infection from other countries. Such, according to this author, are, 1. The plague, which is properly a diſeaſe of Aſia, where it is epidemic. 2. The ſmall-pox, which is an Oriental diſeaſe, and not known to Europe, or even Aſia Minor or Africa, till a ſpice-trade was opened to the remoteſt part of the Indies, whence it originally came, and where it ſtill rages more cruelly than among us. 3. The griping of the guts, which he takes for a diſeaſe peculiar to the Weſt Indies, and yearly received from thence: for this, he adds, is a quite different diſeaſe from the tormina ventris of the ancients, and is ſcarce ever known in the midland counties, or far in the north of England.

EXOUCONTII, in *Church Hiſtory*, a kind of Arian heretics, who maintained that the Son of God was made out of nothing: *i. e.* Ἐκ των εκ οντων, ſuppoſed by Gothofred to be the ſame with the Exocionitæ; but this opinion is contradicted by the authority of Theodoret.

EXPAND, in a *Military Senſe*, relates to the exterior of a line or front, either for the purpoſe of occupying a greater ſpace, or in order to outflank the enemy, thereby to beat in his wings upon his centre.

It is often of the greateſt importance to preſent a more extended line of fire, eſpecially if it can be directed towards any particular ſpot; for inſtance, when a column is iſſuing from a defile, a detroit, or paſs, the enemy will certainly endeavour to pour upon its front as heavy a fire as the ſpace may allow.

Thus, he will probably oppoſe a formidable cannonade thereto, ſo that the ſhots may range along the column, doing great havoc therein, not only among the ſoldiery, but deſtroying the cattle, and diſabling the artillery. The reſt of the field he will generally occupy in an inflected form, preſenting a creſcent; much the ſame as that oppoſed to the immortal Nelſon in his laſt victory! By this means every muſket becomes obnoxious, each being levelled at the head of the column.

If we imagine 3000 men to be drawn up in ſuch a manner as may produce this effect, and that five or ſix guns are brought to bear as above deſcribed, with perhaps a body of cavalry ready to charge in flank, when the column may have proceeded to contend with the centre of the oppoſing force, we ſhall then ſee how neceſſary it is for the column to expand with all poſſible celerity, and not to attempt ſuch an attack before a ſufficient front can be formed to make it with effect.

The mode of expanding may be ſeen under the article Deploy, where this particular operation will be found more fully deſcribed. We ſhall in this place remark, that expanſion is by no means proper where the enemy can bring a large body of cavalry to act in an open country, unleſs an equal number of ſuch troops may be at hand to oppoſe them.

Where a line of intrenchments is to be carried, expanſion is not eligible; yet the concentration muſt be managed with peculiar care whenever the enemy may be able to line their works with artillery, eſpecially howitzers of large calibre, which, by pouring grape among cloſe bodies of men, would ſoon thin their ranks, and probably occaſion, what is delicately called, "a precipitate retreat." The beſt authorities inſtruct us to ſay, that nine battles in ten are loſt by allowing the troops to be too expanded: in ſuch a condition they are every where weak; whereas, when properly concentrated, they are every where formidable.

We may from this collect, that allowing an army to cover too great an expanſe, is, generally ſpeaking, expoſing it to ruin; it enables the enemy to force a line in whichever quarter they may judge proper, and, after forcing it, to cut up the ſeveral parts in detail. Hence, blockades are, with few exceptions, extremely dangerous, as may be better underſtood by reference to *environ*, which ſee.

When a column is to expand or deploy, or when an augmentation of front is to be made, ſuch ought to be done with great promptneſs, and under a heavy fire from each diviſion, ſo faſt as it can arrive at its ſtation in the line. By this means, eſpecially if the wind be favourable, the whole may be done under cover of the ſmoke, and the enemy may be ſo rapidly gained upon, as in turn to render it neceſſary for him to change poſition; but without great coolneſs and firmneſs, nothing will be effected.

EXPANDING Rigger, or *Drum*, in *Mechanics*, is a wheel, or rigger, to receive an endleſs rope, which can be enlarged or diminiſhed in its diameter, to give a greater or leſs velocity to the rope.

The common expanding rigger is a caſt-iron wheel with twelve arms, in each of which a groove is formed, extending nearly from the centre to the circumference, as A A, *fig.* 5. *Plate* XXVI. *Mechanics.* Againſt each arm a piece of wood is placed, which has a rebate fitting into the groove, and a ſcrew-bolt paſſing through both wood and the arm of the wheel; a nut ſcrewed upon the bolt faſtens the bolt and wood at any place in the groove: each piece of wood has a groove in it to receive the rope which paſſes round the wheel. The diameter of this rigger can be altered by looſening the nuts, then placing the pieces of wood all in one circle of the propoſed diameter, and faſtening them there by the nuts. To facilitate the placing of the pieces of wood in one circle, each arm is divided into inches, and numbered from the centre.

Mr. Andrew Flint, of London, lately received a premium of fifty guineas from the Society of Ats, for two expanding band wheels, or riggers. *Figs*. 5, 6, and 7, are different views of the firſt of theſe; A A is a caſt metal wheel with twelve arms, each divided by a groove from near the centre to the circumference: theſe grooves receive rebates on the backs of twelve racks *a a*, *figs*. 6 and 7, which have projecting pieces *b*, *b*, with grooves to contain the endleſs rope *d d*. In *fig*. 5. which is a back view of the wheel *e e*, are nuts, which draw up the racks to ſlide in the grooves without ſhake, yet freely to and from the centre: the racks are moved all together by means of a circular plate *d d*, which has a ſpiral rib upon it entering between the teeth of each rack, ſo that when the plate is turned round, all the racks move to or from the centre at once: the ſpiral plate *d d* is ſcrewed to an iron croſs, which fits upon the axis *f f*, and is turned round by a pinion *g* of ſix teeth, working into a ring of teeth made in the inſide of the ſpiral plate *d*.

Another method of accompliſhing the ſame object is by means of twelve ſcrews *h* (*figs*. 8. and 9) pointing to the centre of the wheel; they are are all moved together by means of equal bevelled wheels fixed on them; by this means the ſcrews are turned about contrary ways alternately: they muſt, therefore, be alternately cut right handed and left handed, that they may produce the ſame effect. The ſcrews are turned, when the diameter of the rigger is to be altered, by a winch put upon any of the three ſquares *h*, *h*, *h*, on the ends of the ſcrews. In this machine the number of ſcrews muſt be even.

Figs. 10, 11, and 12, are drawings of an expanding rigger contrived by the writer of this article: it conſiſts of two wheels of caſt-iron A, A, (*figs*. 10, 11, and 12.) which have ſixteen ſectorial apertures marked *a*, which leave ſixteen arms between them; the arms and the ſpaces are exactly equal, and each arm has a triangular piece of wood *b d e*, (*fig*. 12.) ſcrewed upon it, by four ſcrews going through the arm into the wood, which is alſo kept firm and perpendicular to the face of the wheel, by a rib *f*, (*fig*. 11.) which projects from each arm, and is let into a groove cut in the wood. The wheels have ſockets *g*, *g*, (*figs*. 10 and 12.) which are bored out with a very true cylindrical hole to receive the ſhaft or ſpindle B B of the rigger, which is turned in the lathe to fit the ſockets without ſhake, yet at the ſame time allowing them to move backwards and forwards upon the axis B B. The wheels are put together upon the ſpindle facing each other, the wooden triangles of one wheel entering the ſpace between the arms of the other, as is ſhewn in *figs*. 10 and 12; in this manner it is plain that the points, or rather plane, of interſection of the triangles *b d e* of each wheel, will form a circular groove to receive a rope, which groove can be increaſed in its diameter by advancing the wheels towards each other, or diminiſhed by ſetting them farther apart, as in *fig*. 10. The wheels are prevented from turning on the ſpindle by means of a fillet, which is inſerted partly into a groove cut in the axis, and partly in another groove made in the ſocket of the wheel. The wheels may be brought nearer together, or thrown farther apart, by two ſcrews *h*, *h*, (*fig*. 12.) which have ſockets in one wheel, and are tapped into the other: two equal cog-wheels *i*, *i*, are keyed faſt upon the ſcrews, and an intermediate cog-wheel *k*, placed looſely upon the main axis between them, cauſes both ſcrews to turn at the ſame time. A more ſimple method of altering the diameter is by puſhing the wheels together by hand, and faſtening them to the axis by ſcrews *e*, *e*, *fig*. 10.

EXPANSION, in *Metaphyſics*, expreſſes the idea we have of laſting or preſerving diſtance, *i. e.* of diſtance, all the parts whereof exiſt together.

EXPANSION, from the Latin *expando*, in *Philoſophy*, denotes the increment of ſurface or of bulk, of which natural bodies are ſuſceptible. With reſpect to the expanſion of ſurface, ſee the articles DUCTILITY and GOLD *Beating*.

Bodies of every kind, as far as we are acquainted with them, are expanded in bulk by heat, and are contracted by cold; and to this law there are very few exceptions, which will be noticed in due time. The expanſions, or the increments of bulk, are not exactly proportional to the increments of heat in the ſame body; nor are different bodies expanded alike by the like elevation of temperature. Thus, if a quantity of water be increaſed one inch in bulk, by the communication of ten degrees of heat, the communication of twice or thrice as much more heat will not cauſe it to expand two or three inches more. Alſo, if a rod of gold, and another ſimilar rod of glaſs, be heated to the ſame degree, their increments of bulk, ariſing thereby, will not be equal, the gold expanding more than the glaſs.

Of the three principal ſtates of natural bodies, *viz.* ſolids, liquids, and elaſtic fluids, the ſolids are expanded leaſt; the liquids are expanded more than the ſolids, but the elaſtic fluids are expanded a vaſt deal more than the liquids. The knowledge of the preciſe quantities of theſe expanſions of bodies is of great uſe in philoſophy, in mechanics, and in other ſcientific ſubjects; hence no pains have been ſpared by philoſophers to inveſtigate and aſcertain them; various inſtruments have been contrived for that purpoſe; innumerable experiments have been inſtituted; and a great many uſeful reſults have been obtained. Of theſe reſults we ſhall now endeavour to give a regular and diſtinct account.

The inſtruments which have been contrived for the purpoſe of meaſuring the expanſions of ſolids ariſing from an elevation of temperature, are called *pyrometers*. The objects which muſt be had in view in the conſtruction of pyrometers, are to form a ſteady frame, wherein ſolids of a certain length may be applied either ſucceſſively, or ſeveral of them at the ſame time, ſome contrivance by which thoſe metallic bodies may be heated to any required degree, and a mechaniſm capable of meaſuring the increaſe of bulk which is cauſed by the heat; and this may be accompliſhed by means of multiplying wheels, by levers, by ſcrews, by a microſcopical micrometer, or otherwiſe. See PYROMETER.

Some of the firſt determinations of the expanſion of bodies, that may be conſidered as being ſufficiently accurate, were made by Mr. Ellicot with a pyrometer of his contrivance. Mr. Ellicot determined the proportional expanſions of ſeven metallic bodies by the ſame elevation of temperature. They are as follows:

Gold.	Silver.	Braſs.	Copper.	Iron.	Steel.	and Lead.
73.	103.	95.	89.	60.	56.	149.

Mr. Smeaton contrived a much better pyrometer, and with it he determined the expanſions of ſeveral ſolids. Mr. De Luc alſo contrived a pyrometer of a peculiar conſtruction; but Mr. Ramſden's pyrometer is ſuperior to any other contrivance of the kind.

The following table ſhews, in parts of an inch, how much one foot length of different ſubſtances is expanded by 180° of heat, Fahrenheit's ſcale, between the freezing and the boiling points of water. To the firſt ſeven ſubſtances, (which were examined in Mr. Ramſden's moſt accurate pyrometer,) there are added the expanſions for a ſingle degree of heat. The others were determined by Mr. Smeaton with his pyrometer.

Iron, inſtead of being condenſed into a ſmaller bulk, expands in its tranſition from a fluid into a ſolid ſtate; ſo that a quantity of iron occupies more room in the ſolid form than it does in a fuſed ſtate.

Dr. Wollaſton, in order to form ſome eſtimate of the comparative rate of expanſion of platina and palladium, ſays, "I rivetted together two thin plates of platina and palladium, and obſerving that the compound plate, when heated, became concave on the ſide of the platina; I aſcertained that the expanſion of palladium is in ſome degrees the greater of the two. By a ſimilar mode of compariſon I found that palladium expands conſiderably leſs than ſteel by heat." Phil. Tranſ. for 1805.

It muſt be remarked with reſpect to the expanſion of glaſs, that ſometimes glaſs tubes are extended more than ſolid glaſs rods: their dilatation, however, is not conſtant; for tubes of different diameters, or of different ſorts of glaſs, are expanded differently by the like degrees of heat.

Wood is not expanded much longitudinally; that is, in the direction of its fibres, by heat, and this is particularly the caſe with deal and other ſtraight-grained wood. Probably, upon the whole, the longitudinal expanſion of wood is leſs than that of glaſs. It has been obſerved, (eſpecially by Dr. Rittenhouſe, Tranſ. of the American Phil. Society) that very dry and ſeaſoned wood, if not expoſed to a very high or to a very low temperature, will expand in length pretty regularly: otherwiſe its expanſion by heat, and its contraction by cold, are very irregular: for they ſeem to depend partly upon the heat, and partly upon the moiſture, which the wood acquires in certain circumſtances, and is deprived of in others.

It is hardly neceſſary to mention, that the ſolids of the preceding table contract their dimenſions by cooling as much as they are expanded by heating; thus, for inſtance, if a yard length of any particular metallic body, by being heated 100° above the actual temperature of the atmoſphere, be lengthened one fiftieth part of an inch; afterwards, when cooled down to the temperature of the atmoſphere, it will be found to have loſt exactly that fiftieth part of an inch which it had acquired by heating.

From the experiments hitherto made on the expanſions of ſolids by heat, no correſpondence has been obſerved between the expanſions and the quantities of caloric they are capable of abſorbing. The fuſibility of metals ſeems to coincide with the dilatations; platina, the leaſt fuſible of the metals, dilates the leaſt; lead dilates moſt; and the moſt fuſible glaſs is alſo the moſt dilatable. We may therefore conclude with Mr. Berthollet, that bodies are ſo much the more expanſible, the leſs caloric they require to change their conſtitution from ſolid to liquid, and from liquid to gaſes or vapours.

There is a ſubſtance which expands when heated; but does not contract when cooled; and of this ſingular property Mr. Wedgwood availed himſelf for the conſtruction of his ingenious thermometer for meaſuring the higheſt degrees of heat; *viz.* thoſe degrees which exceed the ſcale of the mercurial thermometer. (See Thermometer.) The ſubſtance alluded to is the argillaceous earth or clay, and it appears that the above-mentioned property belongs, more or leſs, to argillaceous bodies of every kind. This property may at firſt ſight appear to be an unaccountable exception from the general law: the difficulty, however, will vaniſh, if it be conſidered that bodies of the argillaceous genus contain a conſiderable quantity of water, and that the contraction of theſe bodies, when expoſed to the action of a ſtrong fire, is in great meaſure due to the eſcape of the water, and hence they do not contract by ſubſequent cooling.

The method of meaſuring the expanſions of fluids is to incloſe them in a certain veſſel, and to meaſure that part of the cavity of the veſſel, which is occupied by the fluid under trial, in different temperatures. It is evident that the ſubſtance of the veſſel is likewiſe expanded by the heat, and of courſe the cavity of the veſſel is enlarged. Therefore, when we find that the bulk of the fluid is increaſed, that increment is only the difference between the enlarged capacity of the veſſel and the increaſed bulk of the fluid. This ſhews the neceſſity of forming thoſe veſſels of ſuch ſubſtances as are leaſt expanſible by heat. Indeed glaſs is the ſubſtance which is univerſally uſed for ſuch purpoſes, both on account of its little expanſibility, and of its tranſparency; beſides its having other uſeful properties. A glaſs veſſel, filled to a certain degree with a liquid, for the purpoſe of ſhewing the expanſions of that liquid in different temperatures, or for the purpoſe of ſhewing the temperature of the correſponding expanſion of that liquid, is called a thermometer; *viz.* a meaſure of the temperature. See Thermometer.

The propereſt ſhape for a thermometer is that of a long tube with a narrow bore, having a globular cavity at one end; which, familiarly ſpeaking, may be called a globular glaſs bottle with a long and narrow neck. The globular cavity, and part of the tube of one of theſe veſſels, is filled with the liquor whoſe expanſion is to be examined, and the veſſel is then heated, in conſequence of which the liquor, which is contained in it, is expanded, and not being able to extend itſelf any other way, all the increment of bulk muſt be manifeſted in the tube; *viz.* the ſurface of the fluid will riſe in the tube; or, if cooled, it will deſcend in it. If the ſame veſſel of the above-mentioned ſhape be ſucceſſively filled with different fluids, and with each fluid it be expoſed to certain degrees of temperature, (which muſt be determined by an accurate thermometer,) the proportional expanſions of the different fluids may thereby be aſcertained. The ſame object may be obtained by filling ſeveral ſuch veſſels with the different fluids, that are to be examined, and heating or cooling them all at the ſame time; but in this caſe the correſponding capacities of the different veſſels muſt be previouſly aſcertained; which may be done by filling all the veſſels with the ſame kind of fluid, and expoſing them all to different degrees of temperature; ſo that the correſponding elevations of the fluid in the different veſſels may be marked on the tubes. Theſe veſſels are afterwards emptied and filled again with the fluids, &c. Thus the proportional expanſions of liquids may be determined; but when the actual or abſolute increaſe of bulk is required, then the capacity of the veſſel muſt be accurately gauged. This meaſurement of the capacity may be accompliſhed in the following manner. In the firſt place weigh the empty glaſs tube; ſecondly, fill part of the tube with a convenient fluid, (mercury, for inſtance, which is the fitteſt for ſuch purpoſes); thirdly, meaſure the length of the tube which is occupied by the mercury, and weigh the inſtrument a ſecond time; then, by ſubtracting this ſecond weight from the former, you will have the weight of mercury which fills up a certain length of the cavity of the tube; fourthly, fill the bulb of the veſſel entirely with mercury, and weigh the veſſel a third time. This weight being ſubtracted from the firſt, *viz.* from that of the empty veſſel, will leave the weight of the mercury in the bulb. Now, having the weight of the mercury in the bulb, as well as of that which fills a certain length of the tube, the ratio of the former to the latter may be eaſily determined by ſimple diviſion. Alſo the abſolute quantity in bulk of the former is obtained from the well known ſpecific gravity of mercury, and from the weight of a cubic inch of diſtilled water, which (when the barometer is at 29.74 inches, and Fahrenheit's thermometer at 66°) is equal to 252.42 grains Troy; one pound Troy being equal to 5760 of thoſe grains. An Engliſh cubic inch of mercury of the ſpecific gravity 13.6 weighs 3443.2 Engliſh grains. Inſtead of mercury, ſome other fluid may be employed for this purpoſe; but not ſo conveniently as mercury. The expanſions of a fluid, which are cauſed by different degrees of heat, may likewiſe be determined by aſcertaining the ſpecific gravity of that fluid in different temperatures; for the ſpecific gravity decreaſes in proportion as the fluid is expanded, and *vice verſâ;* but this method is not capable of as much accuracy as the former.

Liquids differ from each other in regard to their expanſibility; ſome expanding more than others. Alſo the expanſions of the ſame liquid by equal degrees of heat are not quite regular; and it has been obſerved that this irregularity is greater when they approach the ſtate of vapour. Upon the whole, mercury has been found to be expanded by heat more regularly that any other fluid; yet its increments of bulk are not perfectly regular. Mr. De Luc, with great care and patience, has endeavoured to aſcertain the real expanſibility of mercury, or rather the real quantities of heat that are required for expanding mercury arithmetically, *viz.* by equal augmentations. Theſe are expreſſed in the following table, the firſt column of which contains the degrees of Reaumur's ſcale, from five to five, which are equal parts; the ſecond ſhews the real quantities of heat which are required to raiſe the mercury to the correſponding degrees, where z is a fixt but unknown quantity; and the third column ſhews the differences of thoſe quantities. De Luc's Recher. ſur les Modif. de la Atmoſph. 1772, p. 309.

	Mercurial Thermom.	Real quantities of heat.	Real differences of heat correſponding to the variations of the Mercury in the thermom. from 5 to 5 degrees.
Point of boil. water	80°	z + 80.00	−4.72
	75	z + 75.28	−4.72
	70	z + 70.56	−4.79
	65	z + 65.77	−4.81
	60	z + 60.96	−4.81
	55	z + 56.15	−4.89

	35	z + 36.40	−5.08
	30	z + 31.32	−5.10
	25	z + 26.22	−5.10
	20	z + 21.12	−5.18
	15	z + 15.94	−5.20
	10	z + 10.74	−5.31
	5	z + 5.43	−5.43
Point of melt. ice	0	z	

From the third column it appears, that the differences of heat requiſite to make equal and progreſſive additions to the bulk of the mercury, though not exactly equal, yet are not very far from the ratio of equality. If the bulk of a quantity of mercury, at the temperature of 32° Fahrenheit's ſcale, be conceived to be divided into 100,000 equal parts, and then be heated as high as the temperature of boiling water; (*viz.* 212°) its bulk will thereby be increaſed by 1836 of thoſe parts.

The expanſion of water is attended with a ſingular deviation from the general law; *viz.* this fluid is expanded by heat from about the 40th degree of Fahrenheit's thermometer upwards; but below 40° its bulk is expanded by a farther decreaſe of heat, or increaſe of cold; and in fact ice is lighter than water, ſo as to float upon it; the ſpecific gravity of ice being to that of water nearly as 7 to 8. The bulk of ice is to that of the water, when the ice is melted, as 9 to 8 very nearly. The bulk of water, from its moſt contracted ſtate at the temperature of 40°, increaſes continually; but that increaſe is not very regular; for inſtance, the increaſe of bulk from 180° to 212°, is conſiderably greater than from 40° to 72°. If the bulk of water at 40° be called 1, its bulk at 212° will be 1.04785. Beyond that degree of heat water becomes vapour; *viz.* an elaſtic fluid, and the formation of this elaſtic fluid on the ſides of the veſſel within the water, forms the bubbles, the eſcape of which conſtitutes the boiling. The bulk of ſteam at the boiling point is ſomewhat leſs than 1800 times the bulk of the water from which it originated.

The expanſion of freezing water is not owing to the extrication of air; for water deprived of air expands like other water in freezing. Mr. Mairan attributes it to a ſtrong tendency the particles of water have to arrange themſelves into ranks and lines, which croſs one another at angles of 60° and 120°. This tendency ſeems to begin at the temperature of 40°. The expanſion of freezing water has a prodigious force. It is owing to this that in hard froſts timber is burſt, plaiſter is removed from walls, and even iron mortar ſhells filled with water, and accurately ſtopped, have been burſt by the freezing of the water.

This ſingular property of water, *viz.* its expanding from the temperature of 40° downwards, ſo as to become lighter and lighter in proportion as it becomes colder and colder, is a moſt ſtriking inſtance of the wiſdom of the Creator, and is a property of immenſe conſequence to the very exiſtence of animals and vegetables. A quantity of water is indiſpenſably neceſſary to animals and to vegetables at all times of the year. In winter, when the cold air freezes the ſurface of the water, that effect ſeldom penetrates lower than two or three feet. Below that depth the water continues fluid, and the cruſt of ice itſelf contributes to preſerve its fluidity. The heat of the earth, which has been acquired during the ſummer, undoubtedly prevents the formation of ice below a certain depth. But if water in cooling had continued to increaſe in ſpecific gravity, and had ice been actually heavier than water, the heat of the earth would not have been ſufficient to prevent the total freezing of all the waters of lakes, ſeas, rivers, &c. "For," ſays count Rumford, "as the particles of water on being cooled at the ſurface would, in conſequence of the increaſe of their ſpecific gravity, on parting with a portion of their heat, immediately deſcend to the bottom, the greateſt part of the heat accumulated during the ſummer in the earth, on which the water repoſes, would be carried off and loſt before the water began to freeze; and when ice was once formed, its thickneſs would increaſe with great rapidity, and would continue increaſing during the whole winter; and it ſeems very probable that in climates which are now temperate, the water in the large lakes would be frozen to ſuch a depth in the courſe of a ſevere winter, that the heat of the enſuing ſummer would not be ſufficient to thaw them; and ſhould this once happen, the following winter would hardly fail to change the whole maſs of its waters to one ſolid body of ice, which never more could recover its liquid form, but muſt remain immoveable till the end of time." (7th Eſſay.)

The following table ſhews the expanſions of the principal liquids that have been ſubmitted to ſuch experiments, according to Mr. De Luc's obſervations. With reſpect to this table it muſt be underſtood that different thermometers (each being filled with a particular fluid, ſuch as is mentioned at the top of each column, and each being divided into 80 equal parts between the freezing and the boiling points of water) are placed with their bulbs in the ſame veſſel full of water, and that the water is gradually heated. Then when the mercurial thermometer ſtands at 5°, 10°, 15°, &c. the ſurfaces of the fluids in the other thermometers will be found at the degrees which ſtand on the ſame levels; for inſtance, when the mercurial thermometer ſtands at 40°, the water thermometer will be found to ſtand at 20°.5, the ſpirit thermometer will be found to ſtand at 35°, the oil thermometer at 39°.2, &c.

	Mercury.	Water	Water ſaturated with ſalt.	Alcohol.	Alcohol 3 parts, water 1.	Alcohol and water equal parts.	Alcohol 1 part, water 3.	Oil of olives.

The expanſions of elaſtic fluids, ſuch as common air, the gaſes, and vapours, are more difficultly aſcertained; for the expanſions of thoſe fluids are occaſioned by a diminution of preſſure, as well as by an increaſe of temperature; and it is difficult to ſubject any of thoſe fluids to the action of one of theſe cauſes only at a time, in order that the effect of each may be duly eſtimated.

When common air is acted upon by preſſure only, independent of any alteration of temperature, its bulk is found to increaſe and to decreaſe in the inverſe proportion of the preſſure; thus, the air cloſe to the ſurface of the earth is compreſſed into the bulk which we experience, by the ſuperincumbent atmoſphere. If that preſſure be increaſed, the bulk of the lower air will be contracted, which is manifeſted by an augmentation of its weight; if that preſſure be diminiſhed, the bulk of the lower air will be increaſed, as is manifeſted by a diminution of its weight. And this expanſion and contraction of the air is exactly but inverſely proportional to the preſſure; ſo that a double preſſure will compreſs it into half the ſpace, a treble preſſure into one third of the original ſpace, &c. The ſame thing, *mutatis mutandis*, may be ſaid of the removal of preſſure, and of the expanſion thereby ariſing. This elaſticity of the air has not been found to be impaired by a long continuance of the preſſure; for air has been left during ſeveral years very much compreſſed in proper veſſels, wherein there was nothing that could have a chemical action upon it; and afterwards on removing the unuſual preſſure, and replacing it in the ſame temperature, the air has been found to recover its original bulk. It is not known how far a quantity of air may be expanded by removing the preſſure, nor how much it may be compreſſed by increaſing the preſſure; for no experiments have as yet been able to aſcertain either limit.

The inſtrument, in which the expanſion of air is tried, has been called *manometer*, (which ſee,) It is a ſort of large air thermometer, conſiſting of a tube five or ſix feet long, having a bulb at one end, and being open at the other end. The bore of the tube is about a 20th of an inch in diameter. A ſmall quantity of quickſilver is placed in ſome part of the cavity of the tube, and the expanſion of the air in the bulb, when heated, forces the quickſilver to move towards the open end of the tube. The degree of heat to which the manometer is expoſed is meaſured by means of a thermometer; the quantity of expanſion of the air is meaſured by gauging the manometer, and making marks on the tube, which may indicate parts of the cavity of the tube that are proportional to the capacity of the manometer; as for inſtance 100dths, 1000dths, &c. By placing the manometer horizontal or vertical, either with the bulb downwards or upwards, the air in it may either be left of the natural denſity, or it may be condenſed, or, laſtly, it may be rarefied; for when the manometer ſtands horizontal, the quickſilver in the tube does not preſs upon the air in the bulb, nor on that of the atmoſphere; when the bulb is downwards, the quickſilver preſſes upon the air of the manometer, and when the bulb is upwards, the quickſilver preſſes againſt, and counteracts, in ſome meaſure, the gravity of the atmoſphere. Hence this preſſure, and this expanſion of the air within the manometer, may be increaſed to any required degree by increaſing the quantity of quickſilver within the tube: and thus the expanſibility of common, or of condenſed, or of rarefied air, may be tried. The expanſion of air, by the ſame degrees of heat, differs according to its denſity, and to the quantity of moiſture it contains; nor are the increments of its bulk proportional to the degrees of temperature.

It appears from Col. Roy's very numerous experiments (Phil. Tranſ. vol. 67th) that 1000 parts of air, of the denſity of the common atmoſphere, at 0° of heat, become 1484.21 at 212°; *viz.* are expanded 484.21, by 212° of heat.

1000 parts of air loaded with $2\frac{1}{2}$ atmoſpheres, are expanded 434 of thoſe parts, by 212° of heat.

1000 parts of air preſſed only with $\frac{5}{6}$ths of an atmoſphere, are expanded nearly 484 of thoſe parts by 212° of heat.

1000 parts of air preſſed with $\frac{1}{5}$th of an atmoſphere, are expanded about 141 parts by 180° of heat; *viz.* from the freezing to the boiling point of water.

"From theſe laſt experiments," Col. Roy ſays, "it would ſeem that the particles of air may be ſo far removed from each other, by the diminution of preſſure, as to loſe a very great part of their elaſtic force."

The above-mentioned expanſions of air are by no means regular: *viz.* they are not proportional to the number of the degrees of heat. The maximum of expanſion takes place between 52° and 72°: and the minimum is conſtantly at the boiling point of water. Moiſt air expands a great deal more than dry air, eſpecially when it approaches the boiling point of water; ſo that between 192°, and 212°, moiſt air expands about eight, or nine, times as much as dry air in ſimilar circumſtances.

The expanſions of gaſes may be tried and determined in the ſame manner as the expanſion of common air. From a long ſeries of experiments, Meſſrs. Guyton and Prieur deduced a dilatation peculiar to each gas; but Mr. Guy-Luſſae has ſhewn, that all gaſes, without exception, poſſeſs the ſame expanſibility at the ſame degree of temperature, and that the preſence of water in gaſes occaſioned the errors into which his predeceſſors had fallen. He is led to conclude from his experiments made on gaſes reduced to the utmoſt degree of dryneſs, that 100 parts of each of the permanent gaſes acquire an increaſe of $\frac{1}{213}$ by every degree of the thermometer from 0° to 80° Reaumur's ſcale. Vapours, he alſo thinks, follow the ſame laws of dilatation as gaſes, provided the temperature be ſufficiently elevated to keep them in the elaſtic ſtate. Therefore, Mr. Chaptal ſays, it may be laid down as a principle, that gaſes and vapours are equally dilatable, and equally compreſſible; but it will be neceſſary to be more particular with reſpect to the expanſibility of the vapour of water, upon the elaſticity of which numerous natural phenomena, and the action of ſeveral important machines, depend.

Mr. Schmidt alſo made a ſeries of experiments upon the expanſibility of air, made as dry as poſſible by expoſure to hot potaſh. He found the expanſion of a quantity of air which meaſured one inch at the freezing point, *viz.* at the temperature of 0° Reaumur's thermometer, to expand as below.

Degrees of Reaumur.	Expanſion of one inch.

This table alſo ſhews, by its differing from the reſults of D'Amontons, De Luc, Lambert, Schuckburgh, Berthollet, and others, that thoſe gentlemen operated upon air more or leſs charged with moiſture. They alſo took the barometers at different altitudes. In Mr. Schmidt's experiments the barometer was taken at 29,841 Engliſh inches. Theſe variations of the rates of expanſibility of moiſt air, ſaturated at different temperatures, Schmidt attributes to the variations of the degrees of affinity between air and vapour.

Water heated to the 212th degree of Fahrenheit's thermometer (or thereabout, for the different gravity of the atmoſphere occaſions a conſiderable difference) overcomes the ordinary preſſure of the atmoſphere and becomes ſteam, an elaſtic ſubſtance, the bulk of which at that point is ſomewhat leſs than 1800 times the bulk of the water from which it originated. Beyond that point vapour is expanſible in a moſt aſtoniſhing degree; for 30° more of heat (*viz.* the temperature of 242°) will double the elaſtic force of ſteam; 30° more added to that (*viz.* the temperature of 272°) will render the elaſtic force of ſteam nearly equal to four atmoſpheres; and ſo forth. This immenſe expanſibility of ſteam, when the heat which produces it is quickly ſupplied, is capable of producing prodigious effects. When water is cauſed to boil in a veſſel upon a common fire, the heat which is communicated cannot convert all the water at once into ſteam; but if the quantity of water be ſmall in proportion to the heat which can be communicated in a given time, then the converſion of water into ſteam is quickened to any degree, and it may be rendered inſtantaneous; in which caſe it produces a ſudden and violent expanſion, or an exploſion. A drop of rain in boiling linſeed oil, falls to the bottom, is inſtantly converted into vapour, and occaſions dangerous conſequences. "It has ſometimes," Dr. Black ſays in his Chemical Lectures, "happened that a perſon, by careleſsly ſpitting into a copper foundery, has occaſioned an exploſion that deſtroyed the whole building." Count Rumford attributes the vaſt force of gun-powder to the ſudden converſion into vapour of that quantity of water which naturally enters into the compoſition of that powder; it being a component of the nitre. Phil. Tranſ. for 1797.

Water at the temperature of 212° is converted entirely into ſteam, or rather, under the ordinary preſſure of the atmoſphere, water cannot be heated higher than 212°; but water is gradually converted into ſteam or vapour at a much lower temperature. Mr. Pictet inſtituted a ſeries of experiments on the elaſticity of pure vapour in low temperatures. He found that a grain of warm water in vacuo evaporates in forty minutes in the temperature of 38° Fahr. under a receiver containing 1452 Engliſh cubic inches, but that it did not diffuſe itſelf equally in leſs than ſix hours and then raiſed the hygrometer from 17° to 60°, that is, 43°; and during this whole time the cold under the receiver was conſtantly decreaſing, though ſlowly: which decreaſe undoubtedly contributed to the diffuſion of the vapour. Eſſais de Phyſique, p. 157.

The beſt, or moſt extenſive experiments upon the expanſive force of the ſteam of water, and of the ſteam of alcohol, were made by the Chev. de Bettancourt; and are related by Prony in the ſecond volume of his "Architecture Hydraulique;" from which the following compendious ſketch is derived.

The fluid with which the experiments were made was confined in a very ſtrong copper boiler, being eight inches at its greateſt diameter, and fourteen inches in height. The upper part of it was cloſed by a cover made of copper, through which paſſed three tubes. The firſt ſerved to introduce the fluid into the boiler, and could be cloſed by means of a ſcrew. The ſecond was occupied by a thermometer, having its ball about two inches above the bottom of the boiler, and the ſcale, which was on the outſide, contained from 0° to 110° of Reaumur. To the third was adapted a bent barometer tube, having two lines of internal diameter; the aſcending branch of which was 110 inches in length. By means of a lateral cock a communication was eſtabliſhed between the boiler and an air-pump, which ſerved to make a vacuum before the fire was kindled in the furnace below the apparatus. This circumſtance of evaporation in a vacuum forms an eſſential difference between the experiments of Bettancourt and thoſe made before by Ziegler, and renders them applicable to the theory of the ſteam-engine, where the vapour acts in a ſpace freed from air.

A vacuum having been made in the boiler, the mercury brought as nearly as poſſible to a level in the two branches of the barometric tube, and the thermometer reduced to zero by means of ice, the ice was removed, and a fire was kindled, which was excited gently and with much equality, that the thermometer paſſed over about a degree per minute. One perſon then ſtood by to obſerve the barometer, and another to obſerve the thermometer, and each kept a regiſter from degree to degree of the preſſure and correſponding temperatures; the preſſure being expreſſed by the height, in French inches, of the columns of mercury, which roſe above the level in the long branch of the barometer.

Theſe obſervations of the expanſive force of the ſteam of water furniſh 110 reſults, proceeding from degree to degree of the thermometer, and beginning at zero. Theſe reſults are contained in the following table, where the degrees of preſſure are expreſſed in French inches of perpendicular height of mercury, and the temperature is denoted according to Reaumur's ſcale. The experiments on the expanſive force of the ſteam of alcohol were made by the like proceſs, and with the ſame apparatus.

TABLE of the Expanſive Force of the ſteam of Water and of Alcohol.

The expanſive force of the ſteam of water has alſo been determined by Mr. Schmidt, with all the accuracy that the experiments ſeem to admit of: but the reſults which he has not ſtated for every degree of the thermometer, do not agree exactly with thoſe of Bettancourt. We deem it therefore neceſſary to ſubjoin thoſe reſults in the following ſhort table, wherein the temperature is expreſſed in degrees of Reaumur's thermometer, as in the preceding table, and the expanſive force in French inches of perpendicular altitude of mercury.

Table of the Expanſive Force of the pure vapour of Water, according to Mr. Schmidt.

Temperature.	Expanſive Force.	Temperature.	Expanſive Force.
0	0.0	22	1.01
5	0.11	25	1.30
6	0.15	27	1.42
10	0.28	30	1.93
12	0.38	33	2.23
13	0.44	35	2.68
15	.0.55	37	3.20
16	0.61	39	3.40
18	0.76	40	3.64
20	0.90	80	28.00

Mr. Dalton has likewiſe endeavoured to determine the expanſive force of the vapour of water; but the reſults of his experiments nearly coincide with thoſe of the preceding tables, which ſuperſedes the neceſſity of ſtating them in the preſent article. See Evaporation.

From a careful examination of all the experiments made on this ſubject, Dr. Young has deduced a formula by which the expanſive force of ſteam may be determined for any degree of the thermometer, pretty near the real reſults of the experiments. The formula is as follows:

Let f denote the temperature according to Fahrenheit's thermometer, and e the number of inches in perpendicular height of mercury, which the ſteam is capable of ſupporting; then the formula is $e = .1781\ (1 + .006f)^7$.

The reader might perhaps expect to find in the preſent article the particulars relative to the expanſions of heat, and of electricity; but the uncertain natures of the fluids, to which the effects of heat and of electricity are attributed, beſides other conſiderations, oblige us to refer him to other parts of this Cyclopædia. See Heat, Caloric, and the articles belonging to electricity.

Dr. Gregory, in his Aſtron. p. 407, proves, that a globe of our air, of an inch diameter, if it were removed to the diſtance of a ſemidiameter of the earth, would expand itſelf ſo as to fill all the planetary region as far as, nay, far beyond the ſphere of Saturn. See Air.

EXPANSUM Foliaceum. See Foliaceum.

EX PARTE, i. e. *partly*, or of *one part*, in *Law*. A commiſſion ex parte, is that taken out and executed by one part only; where both parties join it is called a joint commiſſion. See Commission.

Ex Parte Talis, a writ that lies for a bailiff or receiver, who, having auditors aſſigned to take his account, cannot obtain of them reaſonable allowance, but is caſt into priſon. The courſe in this caſe is to ſue this writ out of chancery, directed to the ſheriff, to take four mainpernors to bring his body before the barons of the exchequer at a certain day, and to warn the lord to appear at the ſame time. F. N. B. 129.

EXPECTANT Fee, where lands are given to a man and his wife, and the heirs of their bodies; in which ſenſe it differs from fee-ſimple, where lands are given to a man and his wife in frank marriage, to hold to them and their heirs.

EXPECTANCY, Estates in, are of two ſorts; one created by act of the parties, called a *remainder*; the other by act of law, called a *reverſion*. See theſe articles; and alſo Estate and Executory *Deviſe*.

EXPECTATION, in the *Doctrine of Chances*, is applied to any contingent event, and is capable of being reduced to the rules of computation. Thus, a ſum of money in expectation, when a particular event happens, has a determinate value before that event happens; ſo that if a perſon is to receive any ſum, *e. gr.* 10*l.* when an event takes place which has an equal probability of happening and failing, the value of the expectation is half that ſum or 5*l.* and in all caſes, the expectation of obtaining any ſum is eſtimated by multiplying the value of the ſum expected by the fraction, which repreſents the probability of obtaining it. The expectation of a perſon who has three chances in five of obtaining 100*l.* is equal to $\frac{3}{5} \times 100$ or 60*l.* and the probability of obtaining 100*l.* in this caſe is equal to $\frac{60}{100} = \frac{3}{5}$.

If the obtaining of any ſum requires the happening of ſeveral events that are independent on each other, the value of the expectation of that ſum is found by multiplying together the ſeveral probabilities of happening, and by multiplying the product by the value of the ſum expected. *E. gr.* Suppoſe, that in order to obtain 90*l.* two events muſt happen, one of which has three chances to happen and two to fail, and the other has four chances to happen, and five to fail; the value of the expectation is $= \frac{3}{5} \times \frac{4}{9} \times 90 = \frac{12}{45} \times 90 = \frac{4}{15} \times 90 = \frac{360}{15} = 24$*l.* for if the firſt event had actually happened, the value of the expectation depending ſolely on the ſecond event, would be $\frac{4}{9} \times 90 = 40$*l.* and therefore the happening of the firſt event is the condition of obtaining an expectation worth 40*l.* but the probability of the firſt happening is $\frac{3}{5}$, and the expectation ſought for is evidently worth $\frac{3}{5} \times 40 = \frac{3}{5} \times \frac{4}{9} \times 90 = 24$*l.* The rule will be the ſame if an expectation depends on the happening of one event and the failing of another; and alſo on the failing of two events; and on the happening or failing of any number of events that may be aſſigned. It is here ſuppoſed that the events are independent, or that the happening of one, neither forwards nor obſtructs the happening of the other. But if two events are dependent, *i. e.* if they are ſo connected together as that the probability of either's happening is altered by the happening of the other, the probability of their happening is the product of the probability of the happening of one of them by the probability which the other will have of happening, when the firſt is conſidered as having happened; and the ſame rule will extend to the happening of any aſſigned number of events: thus, in a heap of thirteen cards of the ſame colour, the probability of taking out the ace is $\frac{1}{13}$; and the probability of taking the ace out of another heap of the ſame number is $\frac{1}{13}$; and the probability of both theſe independent events happening will be $\frac{1}{13} \times \frac{1}{13} = \frac{1}{169}$: but the probability of taking the ace firſt out of a ſingle heap of thirteen cards is $\frac{1}{13}$; and that of taking the deuce afterwards is $\frac{1}{12}$; and therefore the probability of both happening is $\frac{1}{13} \times \frac{1}{12} = \frac{1}{156}$. If a perſon has ſeveral expectations on ſeveral ſums, the value of his expectation on the whole is the ſum of his expectations on the particulars: thus, let one event be ſuch, that the probability of obtaining any ſum, *e. gr.* 90*l.* in caſe it happens, may be $\frac{3}{5}$; in which caſe the value of the expectation is $\frac{3}{5} \times 90 = 54$*l.* Let the probability of another event, on which depends a ſecond ſum of 90*l.* be $\frac{4}{9}$, and the value of the expectation in this caſe be $\frac{4}{9} \times 90 = 40$*l.* and the value of the expectation on the whole $54 + 40 = 94$*l.* But if a perſon is to receive 90*l.* once for all for the happening of one or other of the two forementioned events, then the expectation of the firſt event being worth 54*l.* as before, yet the expectation of the ſecond will be different; becauſe this depends on the happening of the firſt, and takes place only in caſe the firſt happens to fail, the probability of which is $\frac{2}{5}$; and on the ſuppoſition of its having failed, the expectation of the ſecond will be 40*l.*; therefore $\frac{2}{5}$ is the meaſure of the probability of obtaining an expectation worth 40*l.*; and conſequently the expectation will be worth $\frac{2}{5} \times 40 = 16$*l.* and the value of the expectation on the whole will be $54 + 16 = 70$*l.* See the farther illuſtration and application of theſe principles and rules in De Moivre's Doctrine of Chances, edit. 3. 1776. See CHANCES and GAMING.

EXPECTATION *of Life*, in the *Doctrine of Life Annuities*, donotes, according to the moſt obvious ſenſe of the term, that particular number of years which a life of a given age has an equal chance of enjoying, or the time which a perſon of a given age may juſtly expect to continue in being. But Mr. Simpſon has ſhewn, that this period does not coincide with what the writers on annuities call the expectation of life, except on the ſuppoſition of an uniform decreaſe in the probabilities of life; and Dr. Price adds, that even on this ſuppoſition, it does not coincide with what is called the expectation of life, in any caſe of joint lives: for two lives of 40 have an even chance, according to Mr. De Moivre's hypotheſis (ſee COMPLEMENT *of life*) of continuing together only $13\frac{1}{2}$ years. According to that hypotheſis, the *probability* that a life aged 40 will continue $13\frac{1}{2}$ years will be expreſſed by $\frac{32.5}{46}$; and this fraction multiplied by itſelf is the probability that two lives of this age ſhall both continue $13\frac{1}{2}$ years; *i.e.* $\frac{32.5}{46} \times \frac{32.5}{46} = \frac{1056.25}{2116}$, equal nearly $\frac{1}{2}$, which repreſents an even chance; but the expectation of two joint lives being (according to the ſame hypotheſis) always a third of the common complement, will be in this caſe $15\frac{1}{3}$ years. Therefore, the expectation of life may ſignify the mean continuance of any given ſingle, joint, or ſurviving lives, according to any given table of obſervations, or the number of years which, taking them one with another, they actually enjoy; ſo that if 46 perſons are alive, all 40 years of age, and one be ſuppoſed to die every year, according to Mr. De Moivre's hypotheſis, till they are all dead in 46 years, half 46 or 23 will be their expectation of life; *i.e.* the number of years enjoyed by them all will be the ſame as if every one of them had lived 23 years, and then died; and ſuppoſing no intereſt of money, the value of an annuity payable for life to every ſingle perſon in ſuch a ſet, would juſt be equal to 23 years purchaſe.

The expectation of life coincides with the ſums of the preſent probabilities, that any given ſingle or joint lives ſhall attain to the end of the firſt, ſecond, third, &c. moments, from this time to the end of their poſſible exiſtence; or (in the caſe of ſurvivorſhips) with the ſum of the probabilities, that there ſhall be a ſurvivor at the end of the firſt, ſecond, third, &c. moments, from the preſent time to the end of the poſſible exiſtence of ſurvivorſhip. From theſe principles Dr. Price has ſhewn how to deduce the demonſtrations of Mr. De Moivre's rules for finding the expectations of lives, which he has omitted; we ſhall here ſubjoin them for the information and amuſement of our mathematical readers. Let $\dot{x}$ ſtand for a moment of time, and n be the *complement* of any aſſigned life; then $\frac{n - \dot{x}}{n}, \frac{n - 2\dot{x}}{n}, \frac{n - 3\dot{x}}{n}$, &c. will be the preſent probabilities of its continuing to the end of the firſt, ſecond, third, &c. moments; and $\frac{n - x}{n}$ the *probability* of its continuing to the end of x time: therefore, $\frac{n - x}{n} \times \dot{x}$ will be the fluxion of the ſum of the probabilities, or of an area repreſenting this ſum, whoſe ordinates are $\frac{n - x}{n}$, and axis x. The fluent of this expreſſion, or $x - \frac{x^2}{2n}$, is the ſum itſelf for the time x; and this, when $x = n$, becomes $\frac{1}{2}n$, the expectation of the aſſigned life, or the ſum of all the probabilities juſt mentioned for its whole poſſible duration. In like manner $\frac{n - x}{n} \times \frac{n - x}{n}$ or $\frac{\overline{n - x}|^2}{n^2}$ is the probability that two equal joint lives will continue x time, and $\frac{\overline{n - x}|^2}{n^2} \times \dot{x}$ will be the fluxion of the ſum of the probabilities; the fluent of which, or $x - \frac{x}{n} + \frac{x^3}{3n^2}$, becomes, when $n = x$, $\frac{n}{3}$, or the expectation of two equal joint lives. Again, ſince $\frac{n - x}{n} \times \frac{2x}{n}$ is the probability that there will be a ſurvivor of two equal joint lives at the end of x time, $\frac{n - x}{n} \times \frac{2x}{n} \times \dot{x}$ will be the fluxion of the ſum of the probabilities; and the fluent, or $\frac{x^2}{n} - \frac{2x^3}{3n^2}$ is, when $x = n$, $\frac{1}{3}n$, or the expectation of ſurvivorſhip between two equal lives, which appears to be equal to the expectation of their joint continuance. The expectation of two unequal joint lives found in the ſame way is $\frac{m}{2} - \frac{m^2}{6n}$, m being the complement of the oldeſt life, and n the complement of the youngeſt. The whole expectation of ſurvivorſhip is $\frac{n}{2} - \frac{m}{2} + \frac{m^2}{3n}$; and the expectation of ſurvivorſhip of the oldeſt will be to that of the youngeſt as $\frac{m^2}{6n}$ to $\frac{n}{2} - \frac{m}{2} + \frac{m^2}{6n}$.

From the definition already given of the expectation of life, it follows, that if in a ſociety limited to a fixed number of members, a 28th part of its members dies annually, 28 would appear to be their common expectation of life at the time they entered; and if it were found in any town or diſtrict, where the number of births and burials are equal, that a 20th or 30th part of the inhabitants die annually, it would appear that 20 or 30 was the expectation of a child juſt born in that town or diſtrict.

Having a table of obſervations, ſhewing the number that die annually at all ages out of a given number alive at thoſe ages, it is eaſy to find the expectation for all ſingle lives by the following rule: divide the ſum of all the living in the table at the age whoſe expectation is required, and at all greater ages, by the number in the table of the living at that age, and ſubtract half unity from the quotient, the remainder will be the expectation required.

The reaſon of this ſubtraction may be underſtood by conceiving the recruit neceſſary to ſupply the waſte of every year to be made always at the end of the year, ſo that the dividend ought to be the medium between the number living at the beginning and the end of the year; that is, it ſhould be taken leſs than the ſum of the living in the table at and above the given age by half the number that die in the year; the effect of which diminution will be the ſame with the ſubtraction here directed. This rule may be illuſtrated by taking the ſum of all the living at 20 and upwards in Tab. I. and dividing it by 360, the number living at that age, and the quotient leſs half unity, will be nearly 28.9 the expectation of 20 in Tab. II.

Table I.—Shewing the Probability of the Duration of Life in London, deduced by Mr. Simpſon from Obſervations on the Bills of Mortality in London for 10 Years, from 1728 to 1737.

Dr. Price has applied his reaſoning on this ſubject to the ſolution of a curious queſtion in political arithmetic, or to determine the number of inhabitants in any place from a table of obſervations, or the bills of mortality for that place, on the ſuppoſition that the yearly births and burials are equal. For this purpoſe find by the table the expectation of an infant juſt born; and this, multiplied by the number of yearly births, will be the number of inhabitants

Were the bills of mortality conſtructed with the leaſt regard to truth, and were a regular account kept of all the perſons who annually migrate from the country, this rule of Dr. Price might be ſafely applied towards aſcertaining the number of inhabitants in London, but in their preſent form the London tables are ſo very incorrect that it can hardly be ſafe to derive any concluſions from them.

It appears from Tab. I. that though an infant juſt born in London has not an equal chance (the probability being $\frac{406}{1000}$) of living three years, his expectation is twenty years, and by Tab. III. that though the expectation of ſuch a child in Northampton is twenty-five, it has only an equal chance of living eight years. This difference proceeds from the greater probability of life in the more mature ages, than in the firſt moments of exiſtence. Were the decrements of life, however, the ſame through every period of it, theſe quantities would always be equal; but as this is not the caſe, neither in the earlier nor the latter ages, the computations founded on ſuch an hypotheſis can in general be of very little uſe. De Moivre's Doctrine of Chances, applied to the Valuation of Annuities, p. 288, &c. Simpſon's Select Exerciſes, p. 253, &c. and particularly Dr. Price's Obſervations on Reverſionary Payments, eſſ. i. vol. ii. or Phil. Tranſ. vol. lix. p. 89. See COMPLEMENT *of Life*, LIFE *Annuities*, MORTALITY, SURVIVORSHIP.

EXPECTATIVE, in the *Canon Law*, a hope founded on a promiſe of obtaining the next benefice that ſhall become vacant, or a right to the reverſion of the next. See BENEFICE.

EXPECTATIVE *Canons*. See CANON.

EXPECTATIVE *Graces*, *Gratiæ Expectativæ*, called alſo *preventions*, were bulls frequently given by the popes or kings for future benefices. The biſhops were exceedingly mortified with them, becauſe they encroached on their privileges; beſides, that ſuch expectatives are odious, as they induce people to wiſh for the death of others.

The uſe of expectatives is very ancient, though it was not near ſo frequent in the firſt ages as afterwards. Originally they were no more than ſimple requeſts made on the part of kings or popes, which the biſhops conſented to with the more willingneſs, as they only preſented to them perſons fit to ſerve the church: but the frequent exerciſe of this privilege made it at length be deemed a matter of obligation and neceſſity.

The council of Trent annulled all expectatives; but the canons relating thereto were never admitted in France, where the right of conferring expectative graces is looked on as one of the regalia.

EXPECTORANT MEDICINES, are thoſe which facilitate the excretion of the mucous diſcharges from the cells and paſſages of the lungs; or *ex pectore*, from the breaſt.

This evacuation muſt be accompliſhed by more or leſs of coughing, which the irritation of the collecting mucus, &c. naturally occaſions. It were, therefore, obviouſly uſeleſs and ſuperfluous to give medicines with a view to excite coughing, (if indeed we were acquainted with any ſubſtance poſſeſſed of ſuch quality,) or to uſe any external means, as the ancient Cnidians are ſaid to have done, for that purpoſe. The principal object, in attempting to facilitate the diſcharge of the contents of the bronchial veſſels and cells, muſt conſiſt in changing the nature of thoſe contents, ſo as to render them thinner, leſs tenacious, and more moveable than before. Whether we are poſſeſſed of any medicines, however, capable of producing ſuch a direct effect, may admit of a queſtion. The generality of writers on the materia medica, and of phyſicians, ſpeak of the utility of ſuch medicines as they have termed *attenuantia* and *incidentia*, for this purpoſe: but we believe, with Dr. Cullen, that their hypotheſis on this ſubject is altogether erroneous, and that no ſuch medicines exiſt. The only probable explanation of the action of an expectorant medicine appears to be, that by increaſing the ſecretion from the exhalent arteries in the lungs, the mucus may be diluted and rendered leſs viſcid and the paſſages from the cells may be more fully moiſtened with a leſs tenacious fluid. We know that there is a conſtant and conſiderable exhalation of moiſture from the cavity of the lungs; and there are many reaſons for believing that this is an excrementitious ſecretion, connected with the other excrementitious ſecretions, particularly with the perſpiration from the ſurface of the body. If, therefore, there are medicines diſpoſed to paſs by perſpiration, it may be preſumed that the ſame are diſpoſed to paſs by the exhalation from the lungs: and this exhalation may not only be increaſed, but the mucus, produced by the follicles, may alſo be poured out in a leſs viſcid form, and conſequently in a ſtate to be more eaſily brought up by expectoration.

It would appear, that ſome ſuch increaſe of the thinner ſecretion of lungs is produced, by ſympathy with the ſtomach, when a condition approaching to nauſea is induced, and that, therefore, medicines which poſſeſs an emetic quality, when uſed in ſmall doſes, operate in ſome degree as expectorants; ſuch as the ſquill, ipecacuanha, nicotiana, antimony, &c. A full doſe of an emetic ſeems to produce this effect more completely, and affords conſiderable relief to thoſe aſthmatic complaints, as they are called, in which the lungs are loaded with a quantity of viſcid phlegm. Many expectorant medicines are mentioned by different writers, ſuch as the tuſſilago, or colt's foot, enula campana, iris florentina, petaſites, &c. which recent experience ſeems to have rejected, from their failure to anſwer the expectation which thoſe writers had excited.

Many other medicines which give relief to coughs have been employed under the appellation of expectorants; but their operation is to be explained upon principles altogether different from that of facilitating expectoration. Among theſe are ſpermaceti, liquorice, oil of almonds, and other vegetable and animal oils, various mucilaginous vegetables, ſuch as mallow, horehound, &c. all of which give a temporary alleviation to the irritation about the glottis, and thus appeaſe the cough, but do not in the ſmalleſt degree aid the expectoration. See Catarrh.

In the chronic coughs of old people, expectoration appears to be facilitated by the uſe of the ſtimulant gums, and of volatile alkali. But perhaps theſe medicines operate indirectly, by ſupporting the ſtrength of the patients, and thus enabling them to uſe greater muſcular exertion in the act of coughing.

EXPECTORATION, the act of bringing up the mucous and other excretions from the lungs, by coughing, hawking, &c. The word has the ſame derivation as the preceding.

EXPEDITATION, in the *Foreſt-Laws*, ſignifies a cutting out the balls of a dog's fore-feet for the preſervation of the king's game.

Every one that keeps any great dog, not expeditated, forfeits three ſhillings and four-pence to the king. In maſtiffs, not the ball of the feet, but the three claws, are to be cut to the ſkin. Inſtit. part. iv. p. 308. "Nullos Dominicos canes abbatis & monachorum expeditari cogat." Chart. Hen. III. "Et ſin quieti de eſpeditamentis canum." Ex. Mag. Rot. Pip. de ann. 9 Ed. II.

The expeditation was to be performed once in every three years, and was done to every man's dog who lived near the foreſt, and even the dogs of the foreſters themſelves.

EXPEDITION, the march of an army to ſome diſtant place, with a view of hoſtilities.

Such were the expeditions of Cyrus againſt Xerxes, and of Bacchus and Alexander to the Indies.

Expeditions for the recovery of the Holy Land were called croiſades.

The ſucceſs of an expedition depends on rapid and unexpected movements. An expedition is planned and governed by the following principal maxims, *viz.* ſecrecy, if poſſible, of preparation, and a concealment of deſign, &c.; a juſt proportion of the means to the end; a knowledge of the ſtate and ſituation of the country, which is intended to be the ſcene of action, and of the place or object that is to be attacked; the appointment of a commander, poſſeſſed of thoſe abilities, and of that diſpoſition, which are adapted to the warfare propoſed; and the arrangement of the plan of the expedition before it is undertaken or carried into effect. The French uſe the word expedition to expreſs any particular military quality, which an officer or ſoldier may poſſeſs. Thus, "cet officier eſt un homme d'expedition," that is, this officer is a man of enterpriſe, or courageous and daring.

EXPENCES, in *Book-keeping*. See Book *of Expences*.

EXPENDITORS, in *Law*, are the perſons appointed by commiſſioners of ſewers, to pay, diſburſe, or expend the money collected by the tax for the repairs of ſewers, &c. when paid into their hands by the collectors on the reparations, amendments, and reformations ordered by the commiſſioners; for which they are to render accounts when required for that purpoſe.

Theſe officers are mentioned in the ſtatute 37 H. VIII. cap. 11. and other ſtatutes. The ſteward who ſuperviſes the repair of the banks and water-courſes in Romney Marſh is likewiſe called the expenditor.

EXPENSE Magazine, is a ſmall receptacle for ſuch quantities of ammunition as may be required on emergency, or for the ſupply of powder, &c. in that ordinary courſe which enables the proper officers to eſtimate with correctneſs what quantity ſhould be kept at hand for the purpoſe of annual exerciſe, or for the furniſhing the neighbouring camps, poſts, or batteries, with ſuch ſtores as may be neceſſary for their uſe. Thus we ſee, in almoſt every fortreſs, various expenſe-magazines built in commodious and ſafe ſituations, for the expreſs purpoſes of enabling the commiſſaries, and the ordnance officers, to prevent the defenders of the ſeveral works in their vicinity from being at a ſtand for want of ammunition. Some of theſe little ſtores are occaſionally built even upon the terre-pleine of the batteries they are to ſupply; but we have heard this practice cenſured; for, though it may be true, that owing to their very ſolid conſtruction they may ſucceſsfully reſiſt the enemies' ſhot, ſtill, as they are liable to explode from other accidents, we cannot join an unqualified approval of ſuch poſitions. We avail ourſelves of a ſuggeſtion offered to us, in which we think the foregoing objection is greatly diminiſhed, if not totally removed. The ſuggeſtion is, that in lieu of allowing any expenſe-magazines to be built on a terre-pleine, a ramp ſhould be thrown up at the back of every ſixth or ſeventh piece of ordnance on the defences, the interior of which ſhould be a magazine of this deſcription. The ramp would ſerve as a paſſage for the perſons employed in conveying the powder to the gunners, and ſhould have a door at that ſide leaſt expoſed to enfilades, or to accidental ſhots. The entrance might, indeed, be either above or below the ramp; though we are diſpoſed to recommend the latter; as the delay occaſioned by aſcending would not be of any conſequence in ordinary defences, and would be fully counter-balanced by the ſafety with which all the expenſe-magazines might be worked. Poſſibly, the ſuggeſtion might be rather improved if the expenſe-magazines were to be built partly under the reſpective ramparts; thereby becoming mines on occaſion. (See *Plate* I. *Tactics*, *fig*. 4.)

Againſt works of maſonry built upon the terre-pleine, we cannot too powerfully inveigh: the immenſe numbers of ſplinters which are generally created by ſuch being ſufficient grounds for their condemnation. If, however, it is deemed proper to have ſmall magazines in ſuch ſituations, (for there may be localities which afford no alternative,) ſuch ought to be ſunk ſo far as to allow the ſummits of their arches to be little more than level with the terre-pleine. Being then covered with ſoil, and well gazoned, (*i. e.* turfed,) they would become uſeful, by cauſing ſuch ſhots as might be ſent over the epaulement to throw up, inſtead of allowing them to trundle along the terre-pleine. (See ENFILADE.)

The entrances of all magazines of this deſcription ought to be towards the back of the battery, and certainly might be rendered ſafer by making a few ſteps down upon the inner revetement; ſo as completely to cover not only the magazine itſelf; but the perſons who might be employed to hand up the cartridges. (See *fig*. 5.)

EXPENSIS *Militum Levandis*, in *Law*, was a writ anciently directed to the ſheriff, for levying allowance for the knights of parliament. See PARLIAMENT, and REPRESENTATIVE.

EXPENSIS *militum non levandis*, &c. an ancient writ to prohibit the ſheriff from levying any allowance for knights of the ſhire upon thoſe that hold lands in ancient demeſne. Reg. Orig. 261.

EXPERIENCE, a kind of knowledge acquired by long uſe without any teacher.

Experience conſiſts in the ideas of things we have ſeen or read, which the judgment has reflected on, to form for itſelf a rule or method.

Authors make three kinds of experience: the firſt is the ſimple uſes of the external ſenſes, whereby we perceive the phenomena of natural things, without any direct attention thereto, or making any application thereof.

The ſecond is, when we premeditatedly and deſignedly make trials of various things, or obſerve thoſe done by others, attending cloſely to all effects and circumſtances.

The third is that preceded by a fore-knowledge, or at leaſt an apprehenſion of the event, and determines whether the apprehenſion were true or falſe; which two latter kinds, eſpecially the third, are of great ſervice in philoſophy.

Dr. Campbell, in his "Philoſophy of Rhetoric," (vol. i. p. 129, &c.) inveſtigates the nature and origin of experience; and obſerves, that thoſe ſources in our natures which give being to it, and conſequently to all thoſe attainments, moral and intellectual, that are derived from it, are ſenſe and memory. The ſenſes, both external and internal, are the original inlets of perception; and the articles of information exhibited by them are devolved on the memory. As remembrance inſtantly ſucceeds ſenſation, the memory becomes the ſole repoſitory of the knowledge received from ſenſe; and hence it is the only original voucher extant of thoſe paſt realities for which we had once the evidence of ſenſe. In order to render the knowledge thus acquired and preſerved uſeful to us, in diſcovering the nature of things and regulating our conduct, a further proceſs of the mind is neceſſary, and this is aſſociation. This retention and aſſociation are called experience. We may here obſerve, that though memory gives birth to experience, which reſults from the compariſon of facts remembered, the experience, or habitual aſſociation, remains, when the individual facts on which it is founded are all forgotten. We cannot purſue the reaſoning of this ingenious writer in his illuſtration of the evidence of experience, which he conſiders as one ſpecies of moral evidence, (analogy and teſtimony being the two others,) and which, in his opinion, is the criterion, if not the foundation, of all moral reaſoning whatever, and the principal organ of truth in all the branches of phyſiology, in the largeſt acceptation of the term. See TESTIMONY.

EXPERIMENT, from the Latin *experimentum*, is a trial, or practical proof of ſomething. In philoſophy it means the reſult of certain applications, diſpoſitions, or combinations, of natural bodies, made with ſome particular view. Experiments are ſaid to be mechanical, or chemical, or electrical, or magnetical, &c. according to the ſubject to which they more immediately belong. The object of making experiments is to aſcertain either certain cauſes or certain phenomena; and for the proper attainment of theſe objects care muſt be had to inſtitute experiments that admit of no equivocal reſult, and ſo as to anſwer the purpoſe in the quickeſt and moſt direct way. The main object, however, of the inquiry can ſeldom be determined by a ſingle deciſive experiment; hence, in moſt caſes, it becomes neceſſary to divide the queſtion into parts, and to aſcertain each part ſeparately by one or more appropriate experiments. When the experiment is ſo preſcribed as to decide the queſtion without any poſſible doubt or equivocation, it has in that caſe frequently been called *experimentum crucis*; meaning a capital or deciſive experiment; ſuch as ſuperſedes the neceſſity of inſtituting more experiments for the ſame purpoſe. The origin of the expreſſion *experimentum crucis* has probably been derived from its being a kind of torture, whereby the nature of the queſtion is, as it were, extorted by force. It has been alſo attributed, though with leſs apparent probability, to the guide or inſtruction which it affords, like that of a direction poſt, which is ſhaped ſomewhat like a croſs.

It is not practicable to give any inſtructions for the right performance of experiments in general; for not only every ſubject, but every particular queſtion belonging to any ſubject, muſt be determined by a peculiar mode of inveſtigation. The experimenter can only be inſtructed by practice. The nature of the ſubject, a ſtrict attention to every apparent circumſtance, an accurate ſtatement of particulars, and an unprejudiced mode of reaſoning, will eaſily ſuggeſt a proper train of experiments which the ſubject in queſtion may admit of. It deſerves to be remarked, that though in the inveſtigation of any ſubject, the philoſopher propoſes a certain order of inveſtigation, (and it is always proper to propoſe to oneſelf ſome ſuch plan or train of experiments;) yet it is but ſeldom that the propoſed plan can, or deſerves to be ſtrictly executed; for the reſult of the firſt or ſecond experiment frequently points out a new track or a more promiſing road; in conſequence of which, new and different trials muſt be inſtituted; and it is in the ready adoption of ſuch plans as may be more ſuited to the laſt indications, that the genius of the philoſopher is rendered conſpicuous.

Such mode may ſuffice for the determination of any doubtful point; but when a diſcovery has been made and is to be explained to other perſons; then it is of uſe to ſhew the ſame reſult by different experiments; for it is not only a ſatisfaction to have ſeveral concurring proofs of the ſame propoſition; but it is alſo rendered intelligible to a greater number of readers or hearers; it being ſeldom the caſe, that the ſame experiment conveys an equal degree of conviction and ſatisfaction to the mind of every body.

EXPERIMENTAL Farm, in *Agriculture*, that ſort of farm eſtabliſhment which is chiefly applied to, or calculated for, the purpoſe of making experiments, with the view of aſcertaining unknown cauſes, effects, or reſults in the various departments of huſbandry. This is a plan which has often been attempted, both individually and collectively, by numbers of perſons warmly intereſted in promoting the improvement of agricultural knowledge; but hitherto, we believe, without that ſort of ſucceſs which might naturally be expected. The cauſe of which has probably been the want of a due combination of real practical agricultural information with that of the ſcientific kind, as without a full comprehenſion of both theſe, in perſons who have the direction and management of ſuch eſtabliſhments, it muſt be utterly impoſſible that they can be ſo highly advantageous as they ought to be. But a writer, who has beſtowed much attention on the ſubject, ſeems to ſuppoſe that there is much doubt of any real benefit being at all produced in this way; as he conſiders both experience and experiment the two means by which facts concerning the art may be aſcertained as equally liable to objection. The term *experience* he conceives to denote thoſe deductions which a perſon draws as the average reſult of practice continued for a conſiderable length of time, and which is unqueſtionably the ſureſt guide that can be followed, where the obſervations are ſufficiently correct, and the circumſtances diſcriminated in ſo clear a manner as to create no ſort of confuſion; ſtill where theſe peculiarities are wanting, the concluſions thus drawn may be extremely fallacious. And what increaſes the evil in this caſe is, that when concluſions have been once drawn in conſequence of an imperfect diſcrimination of circumſtances, there is ſcarcely any chance of eradicating the error; as the mind, when once accuſtomed to think in a certain way, is apt to proceed in the ſame ever afterwards; and that the ſame indiſcrimination which cauſed the firſt error will induce a ſucceſſion of others of the ſame ſort *ad infinitum*. Unfortunately, too, it happens that in agriculture, things which are capable of affecting the reſult of a proceſs or operation, are ſo jumbled and thrown together into one chaotic maſs, that it is a matter of extreme difficulty even for the moſt nice obſerver to diſtinguiſh ſuch as are eſſential, from thoſe which are merely accidental, conſequently extremely eaſy to miſtake one for the other. The inaccuracy likewiſe, which too much prevails in the operations of the farmer, concerning the actual expence of different proceſſes, as affecting any particular object; and all the difficulty of keeping the different produce of different fields ſeparate, render it, in moſt caſes, almoſt impoſſible for the actual farmer to aſcertain, with any ſort of preciſion, either the expence or the value of the produce of any one of his fields; conſequently the profit or loſs of any operation or proceſs is merely gueſſed at, not aſcertained by the teſt of his experience; in conſequence of which he is at liberty, and will of courſe draw the concluſion, which ſeems moſt to confirm his own pre-conceived notion on the head, whatever it may be. Under ſuch circumſtances experience muſt, he conceives, be a very fallacious and imperfect guide. It may, indeed, it is ſuppoſed, furniſh hints or indications of what ought to be purſued or laid aſide and avoided; but that unleſs facts be aſcertained with much greater preciſion than it admits of, they muſt, it is conceived, afford a very unſtable foundation for promoting the ſcientific improvement of agriculture.

In conſequence of which, experiment, he thinks, has been introduced and adapted, in order to ſupply the deficiencies which are thus produced; but which, though, at the firſt ſight, it may promiſe fair to accompliſh ſuch purpoſes, upon a nearer view has not been found adequate in any material degree. An experiment in this art is, it is conceived, a particular operation, undertaken with the deſign of elucidating and explaining ſome fact which is involved in doubt or difficulty; of courſe extreme accuracy, in order to guard againſt every circumſtance that may unintentionally affect or influence the reſult, is an indiſpenſable requiſite in the conducting of it; as, unleſs this be the caſe, the ſame experiment, under different circumſtances, may lead to a variety of concluſions. In general, however, farmers, from their having been but little accuſtomed to the nice diſcriminations of ſcientific inveſtigation, are but indifferently qualified to guard againſt the ſecret influence of cauſes, which they have never even ſo much as ſuſpected of having any power upon the reſult of their experiment. It is, therefore, contended, that from theſe cauſes the experiments made by actual farmers frequently prove extremely defective; and when amateurs of a higher rank project experiments, the detail of them muſt be left to ſervants and dependants, who commonly put down at random all the circumſtances which their careleſſneſs prevented them from noticing; ſo that theſe experiments, though they may aſſume a more engaging appearance of accuracy, are, in fact, for the moſt part, more inaccurate and erroneous than the former. Conſequently, with the view of remedying theſe evils, the notion of an experimental farm has preſented itſelf to many perſons as the only means of forwarding the progreſs of ſcientific agriculture, and upon a ſlight view, the benefits that might reſult from it have indeed ſeemed ſo obvious, that in ſeveral diſtricts of this country funds have been provided, as has been already hinted, for the ſupport of ſuch eſtabliſhments, but on trial they have all found ſuch difficulties in the way, as have not hitherto been capable of being ſurmounted. The chief reaſon of which, it is conceived, is, as has been ſuggeſted before, that of the difficulty of procuring a perſon in every way properly qualified for conducting ſuch an undertaking. On theſe grounds, the expectations of the benefits that are to be derived from the eſtabliſhment of an experimental farm are not by any means ſo great as may be ſuppoſed. It is, indeed, contended, that there are many experiments of the very firſt importance in ſcientific agriculture, which are totally out of, or beyond the ſphere of a farm of this kind. Of this deſcription, it is conceived, are all thoſe facts which have a relation to the original conſtitution of ſoils, and the infinitely diverſified, though little obvious qualities theſe poſſeſs in conſequence of peculiar impregnations, which they may have derived from the operations of nature or of art. It is ſuppoſed that an experimental farm, in ſo far as this particular is concerned, is preciſely the ſame as another farm, in which the experimenter, like the farmer, may in time acquire a knowledge of what will ſuit his own ſoil. But if theſe experiments were preſented to the public under the idea that the reſults which they afforded ſhould be deemed generally concluſive in all diſtricts, ſuch a deciſion would turn out fallacious, as it would ſoon be found, that, in many other caſes, the reſults would be extremely different. Nor is it believed that the practical farmer could derive much advantage from the experimental farm, in what reſpects the economical diſtribution or arrangement of the neceſſary buſineſs which is to be purſued in the conducting of the work, which is a branch of the art that is of the greateſt conſequence to be well underſtood by the real farmer, but that is totally incompatible with the complex arrangements and continually varying operations of the experimental farm.

But however true many of theſe remarks may be, there can be little doubt, but that the eſtabliſhment of experimental farms in different parts of the country muſt, under proper management, be attended with great advantage in throwing additional light on different branches and modes of cultivation, as well as in bringing agriculturiſts acquainted with a variety of new and intereſting facts.

When conducted under a proper ſyſtem of management, farms of this kind might readily aſcertain the following important queſtions.

1ſt. What is the beſt mode of cultivating arable land ?

2d. What is the beſt ſyſtem for the management of graſs land ?

3d. What are the moſt uſeful implements of huſbandry ?

4th. What are the moſt profitable breed of animals, and the beſt, and cheapeſt modes of feeding and fattening them? and,

5th. What is the beſt plan for rendering waſte or barren land productive ?

All theſe queſtions are evidently to be conſidered in relation to the differences of ſoils, circumſtances and ſituations.

Mr. Arthur Young, in ſpeaking of the eſtabliſhment of a farm of this nature, as being properly an undertaking only fit for a ſovereign, in the fourth volume of his "Annals of Agriculture," remarks, that it would have great effects in promoting agriculture in this country, but in others, where that art is ſtill leſs underſtood, it is abſolutely eſſential to the progreſs of it. And that if, in ſome future age, this art, ſo neceſſary to the welfare of mankind, ſhould receive an attention that has hitherto been denied it, and a farm of this ſort ſhould be eſtabliſhed, the following hints may be found of uſe. It is conceived, that a divided attention to complex queſtions ſhould be avoided; and thoſe great leading objects moſt nearly connected with the deficiencies of the national agriculture demand the firſt exertions to aſcertain. With this view the ſoil of the farm ſhould regulate the plan of it. If it were a ſand one in this country, it ſhould, it is ſuppoſed, be thrown into the Norfolk huſbandry, and the object of theſe experiments would be to examine how far that ſyſtem, by means of carrots, turnip-cabbage, and other new plants, equi-diſtant drilling, manuring for the roots and graſſes inſtead of the wheat, &c. could be improved. And connected with this inquiry would be the collateral one of the breed of ſheep, proper for this ſoil; with other objects too numerous to recite, which are at preſent unaſcertained.

If the ſoil were of the clayey or loamy kind, too wet for turnips, the great objects would, it is ſuppoſed, be, the means of baniſhing ſummer fallows, an inquiry of great inportance ; the culture and uſe of cabbages ; the modes of draining by hollow cuts and arched lands ; the beſt means of converting ſuch lands to meadows, and the proper breed of cattle.

And on a loamy ſoil, ſtrongly inclining neither to clay nor ſand, very intereſting inquiries are to be purſued. Every plant, common on all other ſoils, is to be cultivated on this. The rotations of crops; the culture of potatoes and carrots, and their application to all ſorts of cattle; lucerne, and its uſe in ſummer feeding a dairy of cows, that are ſupported in the winter on the roots, &c. are among the numerous inquiries to be proſecuted on this ſort of ſoil. On chalky ſoils the principal object is, it is ſuppoſed, the culture of ſaintfoin, and the beſt means of converting it to corn and turnips preparatory to a renewal.

But on a peat-moor many dubious points are to be aſcertained ; the beſt means of reclaiming, whether by paring and burning, fallow, or mere manuring. The graſſes proper to lay down with ; and the means by roots or cabbages, of ſupporting the greateſt poſſible ſtock of that breed of cattle and ſheep, which are found by experiment moſt proper for the ſoil ; the method of draining, manuring, and giving ſolidity to bogs, &c. Upon all, or either of theſe ſoils, collateral inquiries would ariſe in relation to manures, tillage, inſtruments, &c. and a great variety of doubtful points to be decided in the culture and management of all the plants uſually raiſed on any of them.

A ſmall botanical garden of two or three acres, under a botaniſt, for ſmall experiments upon plants not cultivated but promiſing ; and a laboratory for chemical trials on ſoils, manures, and vegetables, would, it is ſuggeſted, be two neceſſary additions to ſuch an eſtabliſhment ; and with a ſmith's and wheelwright's work-ſhop would render the whole complete.

The great features of ſuch a plan would, it is ſuppoſed, be of utility ; it would, however, be ſuſceptible of no inconſiderable ornament. The lines of the incloſures might be decorated in any imaginable way, provided the contents of the field applicable to uſeful graſs or corn were traced by right lines. Every tract of land, of a conſiderable extent, has ſome broken ground, ſteep ſlopes, water-courſes in glens, or pieces where the plough cannot move with convenience, and where graſs is not an equal object with more level ſpaces ; theſe, by a judicious diſpoſition of the ground, might be connected with the margins of the fields, and, by walks being traced through them, might be made highly ornamental and pleaſing. It is ſuggeſted that one of Brown's winding walks, with its uſual accompaniment of ſhrubs and velvet lawn, ſurrounding thirty, forty, or more acres of graſs, is never ſeen, but it brings to the mind the variety ſuch a ſpace is capable of, by being thrown into experiments that yield a food for the mind as well as the eye. Some delicious ſpots, it is true, unite ſo happily in all their parts, melting by an eaſy gradation into ſo rich a harmony of diſtribution, that any change would offend as much as diſſonance in a piece of pleaſing muſic. But ſuch ſpots are rare : in general, the variety of neat and elegant experiments would not injure the effect at all. The Leaſſowes was, it is ſtated, in all its parts, a farm, and much more agreeable to the eye, than if the whole had been lawn. But in the preſent ſyſtem of decorating ground, variety of effect is wanting ; ſomething to bring variations to the ſcene, in which the owner ſhall be intereſted. The lawn that was ſmooth yeſterday is ſmooth to day, and the revolution of the ſeaſons that bids the roſe breathe its perfume in June, and wither in November, brings to the eye a ſucceſſion of the ſame images which pleaſe this year, as they pleaſed the laſt, without novelty in the cauſe, or increaſe of pleaſure in the effect. The higheſt decoration of landſcape will not give it the power of variety ; it will be the ſame this Auguſt as it was the laſt ; it will be gay in ſummer ; and dreary in December ; its forcible effect is for others not yourſelf ; for at every repetition of viewing the colours fade, and what once excited rapture, now brings no other emotion than cold approbation. The beauty of a mere garden-ſcene is like that of a fine face ; it moves admiration at firſt, and we feel ourſelves under the enchantment of a ſpell that chains all our ſenſes ; but let the enchantreſs ſpeak, and prove herſelf a pretty fool, the inanity of her converſation breaks the ſpell, and ſhe is from that moment leſs than a pretty picture, ſince no one claims a merit in making her. The beauty of a garden-ſcene is much of the ſame kind; it holds little converſation with you; it ſuggeſts no new ideas; it furniſhes no food to an inquiſitive mind. If a perſon be told that he may contemplate the works and wiſdom of God; and hold converſe with the vegetable and animal creation, he replies, not becauſe he is in a garden, for a nettle is as wonderful a production of divine power as a lily, and the ſtructure of a toad an object to philoſophize on, as much as a nightingale. Hence the contemplative pleaſures of a decorated ſcene are not appropriated; they ariſe from the parts and not the combination; and therefore, in this reſpect, might as well not be combined at all. But when the ornamented walks lead you to ſomething that offers novel information with evey ſeaſon, when you are in the purſuit of unknown facts, to aſcertain which is to promote not your own ſolitary pleaſures and contemplations only, but a ſcience intimately connected with the proſperity of a nation; when every incloſure is pregnant with inſtruction, the field of a purſuit, and conſequently of a pleaſure; in ſuch a caſe, it is not a queſtion of an arrangement of a lawn, and water, and ſhade, that ſhall pleaſe the eye for a time; it is not the bloom of a flower, or the bend of a walk, but a ſubject where the renovation of the year brings perennial employment for the mind: your landſcape becomes the ſource of thought; the eye may be pleaſed, but the underſtanding is ſatisfied; and inſtead of modes of duration that have been repeated to ſatiety, a novel ſcene is created, at once the theatre of private pleaſure and public inſtruction; where uſeful knowledge is ſought, not in vain theories, and indolent ſpeculation, but in the vigour and activity of experimental exertion. Compared with ſuch an application of a tract of land, what are parks and gardens, ſhrubberies and decorated grounds, but ſo many baubles to pleaſe children; frivolous efforts to fill the eye, but leave the mind vacant. The prince that raiſes palaces, and embelliſhes the gardens that ſurround them, may be commended for his taſte, and praiſed for his magnificence. Verſailles was called a creation; but had Lewis XVI. eſtabliſhed ſuch a farm as has been deſcribed; had the experiments been regiſtered and publiſhed for the benefit of France; how little would the reputation of that creation now be found, compared with the genuine and never dying fame that would have ſprung from a different application of the ſame ground. The prince that rears a palace, does what princes have done before him; but he who founds an eſtabliſhment for the inſtruction of his people in the moſt neceſſary of all arts, does that which none have done before him, and deſerves a title more truly valuable than that of *Great*, ſo often ill applied to the deſtroyers, not the protectors, of humanity; he will enjoy the title of the "Friend of Mankind."

A late writer on modern huſbandry, however, ſeems to think more favourably of this method of bettering the ſtate of agriculture than the author mentioned above, as he conſiders it as a mean by which a general ſpirit for ſuch improvements may be the moſt effectually introduced. It is a meaſure, he ſuppoſes, which there is every reaſon to believe would be attended with good conſequences, in regard to the determining with exactneſs the proper quantities of the different ſorts of manures that ought to be applied to the different kinds of ſoils; the ſorts beſt adapted to each; and the effects they produce when applied ſingly or in their compound ſtate. But the utility of public experimental farms in every county, if put under the direction and management of perſons of extenſive knowledge and experience, ſhould not, it is contended, be eſtimated by a reference to any particular branch: huſbandry, in all its departments, would be greatly improved in this way; and ſhould the period ever arrive when the obſtacles that ſtand in its way ſhall be removed, and proper means be had recourſe to, for diffuſing a general knowledge of the beſt methods of conducting the various operations connected with that ſcience, that which has been ſuggeſted muſt not be overlooked. It is ſuppoſed that ſuch ſorts of farms would become ſo many ſeminaries, at which youth might be inſtructed in the nature, principles, and practice of agriculture, and to which the common farmer might occaſionally reſort for information, in reſpect to the ſucceſs of experiments made as it were under his own eye, and on ſoils, in ſituations ſimilar to thoſe of his own.

And the author of "Rural Economy of the Midland Counties," in ſpeaking of the advantages of theſe ſorts of farms, aſks, "what man, whether of the ſuperior claſs of yeomanry or tenants, or of a ſuperior claſs of tradeſmen or others, who are now bringing up their ſons to huſbandry, would not, after his ſon had gone through a courſe of private tuition, and received the rudiments of inſtruction from himſelf or ſome profeſſional friend, wiſh to perfect his education in a public ſeminary; where he would have not only an opportunity of ſeeing practice in its higheſt ſtate of improvement, and of converſing with profeſſional men of the moſt enlightened underſtandings; but where he would be duly initiated in the theory of rural knowledge, in the method of making, regiſtering, and obſerving the reſult of experiments; of aſcertaining the inherent qualities, and improving the various breeds of live ſtock; where he would ſee order and ſubordination, and learn the proper treatment of ſervants; and among a variety of other branches of uſeful knowledge, the form and method of keeping farm-accounts, and of aſcertaining with accuracy the profit or loſs upon the whole, and every part of his buſineſs; conſequently of bringing it, as nearly as in its nature it is capable of being brought, to a degree of certainty."

But whatever may be the opinion of ſome concerning the utility of public eſtabliſhments of this nature, we are inclined to believe that they will be found more beneficial when under the direction and management of private individuals who are ſufficiently qualified for ſuch undertakings, for though they may be far leſs extenſive, they will be much more uſefully conducted from their being leſs ſubject to thoſe improper checks and controuls, which are continually taking place when a number of perſons are concerned.

EXPERIMENTAL *philoſophy*. Pythagoras is ſaid to have been the firſt perſon who called himſelf philoſopher, *viz.* a lover of knowledge or wiſdom, from the Greek words φιλος, *a friend* or *lover*, and σοφιας, *knowledge* or *wiſdom*; from which appellation the word philoſophy was derived, meaning the love of general knowledge; and according as this knowledge relates to the manners, the duties, and the conduct of human beings, conſidered in a rational and ſocial light, or to the phenomena of natural bodies, ſo it has been called either *moral philoſophy* (from the Latin *mos* or *mores* its plural, which means *behaviour* or *manners*) or *natural philoſophy*.

The philoſophers of the primitive ages, among the Greeks, Romans, &c. in explanation of the phenomena of nature, ſuch as the motions of the celeſtial bodies, the rain, ſnow, froſt, thunder and lightning, the rainbow, the combuſtion of fuel, the production of animals and vegetables, and ſo forth, generally offered the inadequate ſuggeſtions of their imaginations, which, though moſtly unintelligible, and frequently abſurd in the greateſt degree, were nevertheleſs received with deference by their ſcholars, and were propagated with fidelity or diligence from one generation to another. Their acquieſcence reſted merely on the authority of the teacher. That theſe explanations were generally inadequate and abſurd, is eaſily evinced by obſerving that different contemporary philoſophers entertained and taught opinions diametrically oppoſite to each other, though they related to the very ſame queſtion; and that ſubſequent philoſophers have by actual obſervations, and unerring demonſtrations, ſhewn their fallacy. It may amuſe an inquiſitive mind to obſerve, that whilſt the exertions of the early mathematicians, whoſe productions have obtained the admiration of ſubſequent generations, were ſtrictly rational and correct, the inveſtigations of their contemporary philoſophers were conducted in a manner altogether ſlovenly and ſuperficial. This method of philoſophiſing prevailed for a very long period, and in conſequence of it ſeveral centuries elapſed, during which the knowledge of nature made no progreſs deſerving of notice, excepting a few rare and accidental diſcoveries.

The 15th century, which was productive of the greateſt events and the moſt conſequential diſcoveries that hiſtory can record, ſeems to have given a new turn to the ſubject of natural philoſophy. The old tenets began to be doubted, and the energies of the human mind began to manifeſt their unfettered powers. In the next century, the incoherent dogmas of the preceding ages were freely combated; the authority of names and ſects was diſregarded, and in lieu of opinions, the explanation of natural phenomena was referred to the evidence of actual experiments; and this introduced the appellation of *experimental philoſophy*, meaning the knowledge of natural powers and natural effects, acquired by means of experiments or trials. The leaſt reflection readily ſhewed the ſuperiority of this new method of philoſophiſing; but, independent of any other conſideration, its eſtabliſhment is principally due to the ſucceſs with which it was attended, and which exceeded even the moſt ſanguine expectations of its firſt promoters; for it was no ſooner adopted, than diſcoveries of importance were made, old-eſtabliſhed errors were detected, and the ſubject of philoſophy aſſumed an entirely new aſpect.

It is undoubtedly true, that in this mode of inveſtigation the experiments muſt be preceded by hypotheſis, or ſuppoſition; for a man cannot begin to make experiments without the previous formation of a certain plan; but then the plan, the ſuppoſition, or the hypotheſis goes no farther than to propoſe ſomething, the confirmation or refutation of which is referred to the reſult of experiments, aſſiſted by mathematical calculation.

In the 13th century, the neceſſary preliminaries for the improvement of natural knowledge began to be made; *viz.* collections of what then prevailed under the denomination of ſcientific knowledge, natural knowledge, ſecrets of nature, and the like; and the farrago of truths, errors, inconſiſtencies, doubts, and perplexities, which theſe works contain, is ſtrange indeed. Among the few who effectually began to work in the experimental mode of inveſtigation, during that century, friar Bacon held the moſt diſtinguiſhed place. His deſire of information was great; his views extenſive; his mind clear and capacious; and he is ſaid to have ſpent about 2000*l.* (a ſum very conſiderable at that time) in the performance of his numerous philoſophical experiments. Baptiſta Porta alſo diſtinguiſhed himſelf for ſimilar purſuits in Italy. This inquiſitive perſon lived at Naples, and about the year 1560 formed a ſociety of ſcientific perſons, who met in his own houſe. The great Galileo, who was born in Italy in the year 1564, became famous as a philoſopher and a mathematician towards the latter end of that century and the beginning of the next. His genius, ſuperior to the prejudices of the times, inveſtigated and eſtabliſhed ſeveral leading propoſitions in natural philoſophy; and his ſucceſs, his example, and his precepts diſſeminated an univerſal ardour for the true mode of inveſtigating the powers and the effects of natural bodies. His ſucceſſor, Torricelli, was not unworthy of a moſt diſtinguiſhed rank amongſt the philoſophers of the age; and the Torricellian tube, or the barometer, is a magnificent monument of his experimental inquiries.

In England, as we have already mentioned, friar Bacon was the firſt promoter of true knowledge; but a great part of the work of philoſophical reformation was accompliſhed by another inquiſitive genius of the ſame name. Francis Bacon, lord chancellor of England, gave a freſh and vigorous impulſe to the progreſs of experimental enquiry. He recorded a vaſt number of facts, propoſed and executed a great many experiments; and nothing that related to nature ſeemed to be below his notice.

Theſe early reformers of philoſophy, beſides other obvious difficulties, were obliged to ſtruggle againſt, and the ſucceſs of their labours was much impeded by, the wrong notions which then prevailed, and which had been long rooted in the minds even of the moſt able perſons then living. Galileo was nearly oppreſſed by the ignorance and prejudices of the clergy. Crichton, who flouriſhed about the latter end of the 16th century, wrote an able book expreſsly againſt the vain philoſophy of Ariſtotle, which had long been read in the ſchools. The two Bacons, and other able writers, frequently allude to, and ſtrenuouſly endeavour to remove, the wrong notions of their contemporaries, and, in ſhort, the demolition of the old defective fabric, proved nearly as laborious as the erection of the new ſtructure.

The reform which had been begun by the above-mentioned and other worthy perſons was ſoon after completed by the extraordinary genius of Newton. This truly great man, like a luminary of the firſt magnitude, illuſtrated whatever came within the limits of his notice, and his notice was employed in the greateſt and moſt admired works of the creation. His method was to inſtitute experiments, to examine the phenomena with accuracy, and to ground upon them the ſtricteſt mathematical reaſoning. The conviction which ſuch rational method conveyed, and the numerous diſcoveries with which it was attended, completely exploded the old tenets, and eſtabliſhed the only true method of inveſtigating nature.

The progreſs of experimental philoſophy might have been interrupted by the death of a ſingle individual; for it does but ſeldom occur that genius, health, opulence, and other opportunities concur in the qualification of an experimental philoſopher; but the danger was in great meaſure averted by the inſtitution of philoſophical ſocieties, which, by uniting the efforts of ſeveral ingenious labourers, by furniſhing in great meaſure the means of inveſtigation, by encouraging improvements, and by recording and propagating the reſults, have eſtabliſhed the progreſs of knowledge in a regular and permanent channel.

The firſt ſociety of the kind which we find recorded, is that which we have already mentioned at the houſe of Baptiſta Porta in Naples, towards the latter end of the 16th century. It was called "Academia Secretorum Naturæ." Next to this, and before the end of the ſame century, the Academy, called of the Lyncei, was founded at Rome, and was rendered famous throughout the world principally by the renown of one of its members, the great Galileo. The Academy del Cimento, and ſeveral other aſſociations of ſcientific perſons, were eſtabliſhed in the ſucceeding, *viz.*

the 17th century. And amongſt thoſe aſſociations the firſt rank muſt be aſſigned to the Royal Society of London. This moſt learned and diſtinguiſhed ſociety had its origin ſoon after the middle of the 17th century. A few men of learning began to meet at ſtated times in Wadham college, Oxford; and among thoſe perſons there were the following conſpicuous characters; *viz.* Dr. Ward, Robert Boyle, Dr. Wilkins, ſir William Petty, Mr. Matthew Wren, Dr. Wallis, Dr. Goddard, Dr. Willis, Dr. Bathurſt, Dr. Chriſtopher Wren, and Mr. Rooke. From Oxford this aſſociation transferred its meetings to Greſham college in London, which took place in the year 1658. There they increaſed their number, and ſoon after the reſtoration of Charles II. that ſociety received a royal charter, which eſtabliſhed it into the form that has been continued ever ſince; but we muſt refer the reader to other articles of this Cyclopædia for the particular account of the Royal Society of London, as well as of other ſcientific aſſociations in this and other countries; and at the ſame time we muſt proceed to explain the new mode of philoſophiſing in a manner ſomewhat more particular.

The objects of the univerſe, or the natural bodies, which affect our ſenſes, become known and uſeful to us by their properties, ſome of which affect one of our ſenſes, whilſt others affect ſome other ſenſe. Thus we perceive luminous bodies through our eyes, ſound through our ears, heat or cold by the touch or feel, &c. Some of theſe properties are called general, like gravity and extenſion, becauſe they belong to all bodies; and others, like tranſparency and fluidity, are called particular, becauſe they belong to certain bodies only. The better we become acquainted with the properties of natural bodies, the more extended the ſphere of our powers and of our advantages becomes; and it is for the diſcovery of theſe properties, either in ſimple or in compound bodies, that experimental inquiries are inſtituted.

In the acquirement of knowledge, the human being has no other aſſiſtance beſides that of his ſenſes, and of his reaſoning faculty. By the firſt he obſerves and acquires ideas of ſelf evident propoſitions, or properties of natural bodies; ſuch as the human mind cannot diſſent from without manifeſt violence; by the ſecond he is led from one of theſe evident ſimple propoſitions, to another ſtrictly depending upon the firſt, then to a third ſtrictly depending upon the ſecond, and ſo on, to the acquiſition of ſome idea more complex, and leſs apparent at the firſt annunciation.

The conſtant obſervations of philoſophers, with ſir Iſaac Newton at their head, and the dictates of plain reaſoning, have furniſhed certain axioms and certain rules of philoſophizing, the propriety of which is too evident to be objected to.

The axioms of philoſophy, or the axioms which have been deduced from common and conſtant experience, are ſo evident, and ſo generally known, that it will be ſufficient to mention a few of them only.

1. Nothing has no property; hence

2. No ſubſtance, or nothing can be produced from nothing.

3. Matter cannot be annihilated, or reduced to nothing.

The propriety of the laſt axiom may perhaps be not readily admitted by certain perſons; obſerving that a great many things appear to be utterly deſtroyed by the action of fire; alſo that water may be cauſed to diſappear by means of evaporation, and ſo forth. But it muſt be obſerved, that in theſe caſes the ſubſtances are not annihilated; they are only diſperſed, or removed from one place to another, and by being divided into particles very minute, they elude our ſenſes, and eſcape our immediate notice. Thus, when a piece of wood is placed upon the fire, the greateſt part of it diſappears, and a few aſhes only remain, the weight and bulk of which do not amount to the hundredth part of the weight and bulk of the original piece of wood. In this caſe the piece of wood is divided into its conſtituent principles, which the action of the fire drives different ways. The fluid part, for inſtance, becomes ſteam, the light coaly part either adheres to the chimney, or is diſperſed through the air, &c. ſo that if, after the combuſtion, the ſcattered materials were collected, (which may in great meaſure be accompliſhed,) the ſum of their weights would equal the weight of the original piece of wood.

4. Every effect has, or is produced by, an adequate cauſe, and is proportionate to it.

It may in general be obſerved, with reſpect to theſe axioms, that we only mean to aſſert what has been conſtantly ſhewn, and confirmed by experience, and is not contradicted either by reaſoning or by any known experiment. But we do not mean to aſſert that they are as evident as the axioms of geometry; nor do we in the leaſt preſume to preſcribe limits to the agency of the Almighty Creator of every thing, whoſe power and whoſe ends are too far removed from the reach of our underſtandings.

Having thus ſtated the principal axioms of philoſophy, it is in the next place neceſſary to mention the rules of philoſophizing, which have been formed, after mature conſideration, for the purpoſe of preventing errors as much as poſſible, and of leading the ſtudent of nature along the ſhorteſt and ſafeſt path to the attainment of true and uſeful knowledge. Theſe rules are not more than four; *viz.*

1. We are to admit no more cauſes of natural things, than ſuch as are both true and ſufficient to explain the appearances.

2. Therefore to the ſame natural effects we muſt, as far as poſſible, aſſign the ſame cauſes.

3. Such qualities of bodies as are not capable of increaſe or of decreaſe, and which are found to belong to all bodies within the reach of our experience, are to be eſteemed the univerſal qualities of all bodies whatſoever.

4. In experimental philoſophy we are to look upon propoſitions collected by general induction from phenomena, as accurately or very nearly true, notwithſtanding any contrary hypotheſes that may be imagined, till ſuch time as other phenomena occur, by which they may either be corrected, or may be ſhewn to be liable to exceptions.

With reſpect to the degree of evidence which ought to be expected in natural philoſophy, it is but proper to remark that phyſical matters are not in general capable of ſuch abſolute certainty as the branches of mathematics. The propoſitions of the latter ſcience are clearly deduced from a ſet of axioms ſo very ſimple and evident, as to convey perfect conviction to the mind; nor can any of them be denied without a manifeſt abſurdity. But in natural philoſophy we can only ſay, that becauſe certain particular effects have been conſtantly produced under certain circumſtances, therefore they will moſt probably continue to be produced as long as the ſame circumſtances exiſt; and likewiſe that they do, in all probability, depend upon thoſe circumſtances. And this is what we mean by *laws of Nature; viz.* certain effects which are or have been uniformly produced by certain cauſes, as far as our obſervations reach.

We may, indeed, aſſume various phyſical principles, and by reaſoning upon them, we may ſtrictly demonſtrate the deduction of certain conſequences. But as the demonſtration goes no farther than to prove that ſuch conſequences muſt neceſſarily follow the principles which have been aſſumed;

the conſequences themſelves can have no greater degree of certainty than the principles are poſſeſſed of; ſo that they are true, or falſe, or probable, according as the principles upon which they depend are true, or falſe, or probable.

The foundations of experimental philoſophy, as we have already obſerved, are the properties of natural bodies, *viz.* of all thoſe bodies, either ſolid or fluid, which in any way affect any of our ſenſes: and ſince our ſenſes are affected by the properties of theſe bodies, *viz.* by their extenſion, colour, hardneſs, tranſparency, &c. we cannot know any more of theſe bodies than what is manifeſted to us by ſuch properties only as we are able to perceive. Were we furniſhed with other ſenſes, we might diſcover other properties which would make us more intimately acquainted with the nature of ſuch bodies.

Human art has not been able to diſcover more ſenſes than thoſe which every body knows; but it has, in great meaſure, improved ſome of thoſe which we poſſeſs, and this alone is ſufficient to point out the limited nature of our perceptions. Thus, for inſtance, the diſcovery of the microſcope, and the teleſcope, have ſhewn us wonders of which our forefathers were utterly ignorant; and the number and variety of theſe wonders have increaſed in proportion as the above-mentioned inſtruments have been improved. The improvements of theſe inſtruments have been ſuggeſted by the diſcoveries that have been made reſpecting the refrangibility of light, and the properties of tranſparent bodies, and theſe have been made in conſequence of the innumerable experiments that have been inſtituted by various intelligent perſons. Thus it appears, that by means of trials and obſervations new facts are aſcertained, which, beſides their being immediately uſeful to the human ſpecies, furniſh, at the ſame time, the means of making farther diſcoveries; and the treaſures of the natural world are far, indeed, from a ſtate of exhauſtion. Hence the improvements and the diſcoveries of experimental philoſophy proceed in a kind of increaſing geometrical progreſſion; unleſs they be impeded by ſome extraordinary occurrence.

In contemplating the intimate nature of natural bodies, when our mind goes beyond the bounds of our ſenſes, (and our ſenſes, even with the aſſiſtance of inſtruments and reaſoning, are only capable of perceiving a few properties of thoſe bodies;) we wander in the boundleſs field of probability and conjecture. Two principal hypotheſes have been entertained with reſpect to the primitive component particles of bodies. One is, that the particles of each peculiar ſpecies of bodies are different from the particles of another ſpecies of bodies. Thus the primitive particles of gold are ſuppoſed to be different from the particles of calcareous earth, different from the particles of water, &c. The other hypotheſis is, that there is one kind of primitive or original particles of matter, and that from the different arrangement of thoſe ultimate particles, the various bodies ariſe. Experience ſhews that certain bodies, which, at firſt ſight, appear to be abſolutely different from each other, are, upon further examination, exactly of the ſame nature. On the other hand, a vaſt number of bodies are ſo diſtinct from each other, that no art has been able to form one of them from the particles of another; thus gold cannot be converted into a diamond, iron cannot be converted into lead, &c. The former of theſe obſervations ſeems to favour the ſecond hypotheſis; the latter ſeems to favour the firſt hypotheſis; but it is not in our power to determine the real ſtate of the matter.

With reſpect to the number of bodies, which, by our not being able to change one of them into the other, are called elementary, or primitive and diſtinct, the reader will find ſufficient information under the article Element; but it may be remarked in this place, that new bodies are frequently diſcovered in proportion as new inſtruments, and the improvements of ſcience in general, furniſh us with the means of diſcriminating them from others; hence we are naturally led to conclude, that moſt probably there may exiſt a vaſt number of other bodies, of which we at preſent have not the leaſt ſuſpicion. Some of theſe may perhaps be diſcovered hereafter, whilſt others may remain utterly unknown to the human ſpecies.

The properties of natural bodies, which are the objects of reſearch to the experimental philoſopher, are either general, or particular. The general properties, which belong to all kinds of bodies, are, as far as we know, not more than ſix; *viz.* extenſion, diviſibility, impenetrability, mobility, vis inertiæ, or paſſiveneſs, and gravitation. We have ſaid that theſe are the general properties as far as we know, becauſe matter in general may poſſeſs other properties that are not yet come to our notice. And the ſame obſervation may be made with reſpect to the univerſality of theſe properties: for they are ſaid to be general, becauſe no body was ever found which wanted any one of them. But mankind are not acquainted with all the bodies of the univerſe, and even ſeveral of thoſe which are known to exiſt, cannot be ſubjected to experiments.

The peculiar properties, *viz.* thoſe which belong to certain bodies only, and not to others, are denſity, rarity, hardneſs, ſoftneſs, fluidity, rigidity, flexibility, elaſticity, opacity, tranſparency, the properties of light, the properties of heat, the properties of electricity, the properties of magnetiſm, and three other kinds of attraction, (independent of gravitation, of electricity, and of magnetiſm,) *viz.* the attraction of aggregation, which the homogeneous parts of matter have towards each other, or by which they adhere together; and ſuch is the power by which two ſmall drops of mercury, when placed contiguous to each other, ruſh, as it were, into each other, and form a ſingle drop; the attraction of coheſion, or that power by which the heterogeneous particles of bodies adhere to each other without any change of their natural properties, ſuch as the adheſion of water to glaſs, of oil to iron, &c.; and the attraction of compoſition, or of affinity, which is the tendency that the parts of heterogeneous bodies have towards each other, by which they combine, and form a body, differing more or leſs from any of its components.

It is to be remarked, that of all theſe properties we know their exiſtence only, and ſome of the laws under which they act; but we are otherwiſe utterly ignorant of their nature and dependence.

The inveſtigation of ſome of the above-mentioned properties, whether general or particular, has been carried much farther than the inveſtigation of other properties. The reſults of theſe inveſtigations have likewiſe been various, both in point of extent and of application. Some of them are ſo very extenſive and ſo uſeful, as to form the foundations of very important branches of ſcience or of art, under peculiar appellations. Thus, upon the mobility and the vis inertiæ of bodies, the doctrine of motion, or dynamics, is grounded, which comprehends mechanics, hydroſtatics, or the mechanical properties of fluids, pneumatics, &c. Tranſparency and the properties of light form the important foundation of optics. The attraction of affinity is the foundation of chemiſtry, as well as of various arts, and ſo forth. Whatever belongs to theſe properties, or to the extenſive ſubjects that are grounded upon the ſame, will be found under the various articles of their peculiar denominations.

The phenomena of the univerſe, are the appearances which take place in conſequence of the above-mentioned properties of natural bodies, together (reſpecting ſome of them at leaſt) with ſome original impulſe. The phenomena which take place amongſt the luminous celeſtial bodies, properly ſo called, ſuch as the ſtars, the planets, &c. are examined by a particular ſcience called aſtronomy; the meteors, or the phenomena, which take place within the limits of the terreſtrial atmoſphere, ſuch as ſhooting ſtars, northern lights, halos, rain, fogs, hail, winds, &c. form the ſubject of meteorology. The phenomena that take place upon the ſurface of, or within, the earth, are treated of under the comprehenſive denominations of *vegetation, earthquakes, volcanoes, combuſtion,* &c. all which will be found explained under their appropriate articles.

EXPERIMENTUM Crucis, denotes a capital, leading, or deciſive experiment; thus called, either, becauſe like a croſs or direction poſt, placed in the meeting of ſeveral roads, it guides and directs men to the true knowledge of the nature of the thing they are enquiring after; or as it is a kind of torture, whereby the nature of the thing is, as it were, extorted by violence.

EXPIATION, the act of ſuffering the puniſhments adjudged to a man's crimes, and thus paying off, or diſcharging the debt or guilt; and it is figuratively applied to the pardon procured for the ſins of the penitent by the interpoſition and death of Chriſt.

The Romaniſts hold, that ſouls after death are ſent to purgatory to expiate or atone for their ſins. See Purgatory.

Expiation is alſo applied to ſacrifices offered to the Deity, to implore his mercy and forgiveneſs.

Expiation, *the Feaſt of,* among the Jews, called by our tranſlators the *day of atonement,* was held on the tenth day of Tiſri, or the ſeventh month of the Jewiſh year, anſwering to part of our September and October. It was inſtituted by God himſelf, Levit. xxiii. 27, &c. On that day the high-prieſt, the figure or type of Jeſus Chriſt, entered into the moſt holy place, and confeſſed his ſins; and, after ſeveral ceremonies, made an atonement for all the people to waſh them from their ſins. Lev. chap. xvi. See Scape-*Goat.*

Expiation, among the *Heathens,* denoted a purification uſed for effacing or aboliſhing a crime, averting any calamity; and on a thouſand other occaſions, as purifying towns, temples, and ſacred places, and armies, before and after battle.

It was practiſed with divers ceremonies: the moſt uſual was ablution.

Expiations were performed for whole cities as well as particular perſons. After the young Horatius had been abſolved by the people for the murder of his ſiſter, he was farther purified by ſeveral expiations preſcribed by the laws of the pontifices for involuntary murders. Dion. Halicarnaſſ.

EXPILATION, from *expilo, I rob,* in the *Civil Law,* the act of withdrawing or diverting ſomething belonging to an inheritance, before any body had declared himſelf heir thereof.

This made a peculiar ſpecies of theft; for there could not properly be a theft in taking a thing not poſſeſſed by any body, or before the inheritance was accepted.

For this reaſon the Roman legiſlature introduced the action of expilation for the puniſhment of this crime.

Beſide this meaning, it was uſed in a more ſpecial manner to ſignify a robbery committed by night; whence an expilator was looked upon as a greater criminal than a common thief.

The expilators were ſo called from their robbing and ſtripping people of their cloaths.

EXPIRATION, in *Phyſiology,* is the act of expelling air from the lungs, produced by a diminution of the cavity of the cheſt. It is oppoſed to inſpiration, in which air is drawn into the cheſt. See Respiration.

Expiration is alſo uſed figuratively, for the end of a term of time granted, or agreed on, or adjudged.

EXPLEES, in *Law,* the rents or profits of an eſtate, &c. See Esplees.

EXPLICATION *of the Subject of a Diſcourſe,* in *Pulpit Oratory,* and in the compoſition of ſermons, comes in the place of narration at the bar, and ſhould be conducted in a ſimilar manner. It ſhould be conciſe, clear, and diſtinct, and in a ſtyle correct and elegant, rather than highly adorned. To explain the doctrine of the text with propriety, to give a full and perſpicuous account of the nature of that virtue or duty which forms the ſubject of the diſcourſe, is properly the didactic part of preaching; on the right execution of which much depends for all that comes afterward in the way of perſuaſion. The great art in ſucceeding in it is, to meditate profoundly on the ſubject, ſo as to place it in a clear and ſtrong point of view. Conſider what light other paſſages of ſcripture throw upon it; conſider whether it be a ſubject nearly related to ſome other from which it is proper to diſtinguiſh it, conſider whether it can be illuſtrated to advantage by comparing it with, or oppoſing it to, ſome other thing; by enquiring into cauſes, or tracing effects; by pointing out examples, or appealing to the feelings of the hearers; that thus a definite, preciſe, circumſtantial view may be afforded of the doctrine to be inculcated. Let the preacher be perſuaded, that by ſuch diſtinct and apt illuſtrations of the known truths of religion, it may both diſplay great merit in the way of compoſition, and, what he ought to conſider as far more valuable, render his diſcourſes weighty, inſtructive, and uſeful. Blair's Lectures, vol. ii. p. 297.

EXPLICATIVE Proposition, in *Logic.* See Complex *Propoſition.*

EXPLICITE, in the *Schools,* ſomething clear, diſtinct, formal, and unfolded.

The will or intention is ſaid to be explicite when it is fully explained in proper terms; and implicite, when it is only to be learnt by deductions and conſequences.

The Jews had not all an explicite knowledge of Jeſus Chriſt, but they had at leaſt an implicite one.

Such a teſtator has declared his will explicitely, *i.e.* in formal terms; there is no need to have recourſe to explications.

EXPLOITS, Bay *of,* in *Geography,* a bay of the Atlantic, on the eaſt coaſt of Newfoundland. N. lat. 49° 45′. W. long. 55° 20′.

EXPLOSION. It is a matter of great moment, in military engineering, ſo to load, and indeed to conſtruct, a mine, that it may explode with the greateſt preciſion, and with the maximum effect. A variety of theories has been given upon this ſubject, but it would be out of place to notice the whole of what appertains thereto in this place; therefore we ſhall refer our readers to the word Mine for the particular detail of what relates to this ſubject, contenting ourſelves with now offering a few remarks on the manner in which the exploſion is uſually effected.

It is of the firſt importance to aſcertain, ſo nearly as may be practicable, what depth, and what weight of ſoil is to be removed by an exploſion. This being done, the mine is formed, by a gallery leading to the chamber in which the powder is to be depoſited in a very ſtrong cheſt, let into a receſs, and firmly ſecured in every part. Now, it being the nature of the rarefied air to eſcape by that part which may be the weakeſt, it is evident, that if a mine is made under a rampart, ſo as to be within ſix feet of the ſurface, while all the ſides are thicker by far than that meaſurement, the exploſion will be directed towards that part which is thinneſt, and which from that circumſtance is called "the line of leaſt reſiſtance."

But, in order to direct the exploſion to that part, it will be neceſſary to conſider whether the ſoil be every where alike; for if the ſuperincumbent portion ſhould be part of a large ſtratified rock, while the ſides are of a looſe, inadheſive ſubſtance, the latter, though meaſuring more in diameter, will give the line of leaſt reſiſtance, which, in ſuch caſe, would follow the intenacity, and create a falſe exploſion. Hence exploſions may be lateral as well as vertical.

It was formerly ſuppoſed, that the diameter of the entonnoir, or exploſion, was equal to double the line of leaſt reſiſtance; but we find that *ſix times* that line may be exploded, by allowing a load of 300lbs. of gun-powder, duly concentrated, and fired in the middle of the maſs, for every foot of the line of leaſt reſiſtance. We are not to infer from this, that 300lbs. will be requiſite to lift one foot of ſoil; far from it; for as a cubic foot of excavation will contain only 75lbs. of powder, the above quantity (300lbs.) would require a ſpace of exactly four cubic feet; the proportion would therefore be prepoſterous. But when we calculate upon large maſſes of ſoil, ſuch as thoſe prodigious cones thrown out from entonnoirs of great extent, we then find, that, to produce the completeſt exploſion, an immenſe quantity of powder muſt be ſupplied.

It is ſelf evident, that the power of the powder, according to the above ſcale, is only computed to that extent which may be neceſſary towards the ordinary purpoſes of military devaſtation; for if we were to contribute, *ad infinitum*, 300lbs. of gunpowder for every foot in the line of leaſt reſiſtance, we ſhould be accumulating power only in arithmetical proportion, while the reſiſtance would be increaſing in a geometric ratio: of courſe the power muſt be in a regular ſtate of comparative diminution, in proportion as the line of leaſt reſiſtance is increaſed; and this muſt, after a while, occaſion the powder to be inert; or, if there ſhould be any exploſion, it could only follow the track of the train; its ignition to be ſure might be felt partially, like that of a ſlight earthquake, but no ſuperficial effects would be obſervable.

It has been already ſtated, that the powder muſt be lodged in bulk; and that it ſhould be ignited at the centre. This may, perhaps, appear ſuperfluous; but all military men know, that much powder is blown out of the muzzles of pieces without ever being ignited; and we have a moſt remarkable fact, a very recent one indeed, which ſhews that, unleſs in bulk, powder is not always ſure to be fired *in toto*. The incident alluded to is as follows.

In the month of March of this year, (1809,) a barge was proceeding along the new cut, from Paddington, laden with caſks of ſpirits and barrels of gunpowder. One of the crew, it is ſuppoſed, allured by the former, bored a hole for the purpoſe of drawing off a little wherewith to tipple. Unhappily the action of the gimblet ſet fire to the contents of that barrel, which the diſhoneſt navigator had miſtaken for one of ſpirits. The barrel exploded; and drove eleven other barrels, filled with gunpowder alſo, to the diſtance of near a hundred and fifty yards. It is curious, that although the whole of the powder-barrels were together, indeed in contact, only that in queſtion exploded.

Vauban gives us the following ſcale for exploding ſoils of various deſcriptions. He calculates, or perhaps found from experience, that for a cubic fathom (ſix feet) of ſoil, meaſuring in all 216 ſolid feet, the following proportions of gunpowder were needful.

1. Light earth, mixed with ſand,	11lb.
2. Common earth	12
3. Strong ſand	15
4. Clay, or fat earth,	16
5. Old, and good maſonry	18
6. Rock	20

In following this calculation, we are to conſider the entonnoir to be in diameter equal to only double the line of leaſt reſiſtance; and not according to a maximum exploſion.

Exploſion, from the Latin *explodo*, is the act of driving out ſomething with noiſe and violence. The cauſes, the report or noiſe, and the other effects of exploſions, however inſignificant they may appear at firſt ſight, are nevertheleſs, when duly conſidered, of great conſequence to the human ſpecies, and as ſuch they have been carefully inquired into by divers philoſophers. A variety of experiments have been inſtituted for determining the particulars that relate to them, and numerous conjectures have been offered in explanation of theſe concomitant circumſtances, which have not as yet been thoroughly inveſtigated.

Exploſions may be diſtinguiſhed into natural and artificial. The principal natural exploſions are thoſe of the atmoſpherical thunder, of volcanoes, of earthquakes, and to theſe there may be added the inferior exploſions ariſing from hard froſts. The artificial exploſions are ſuch as are produced by the force of fired gunpowder in the various engines in which it is uſed, the exploſions produced by other chemical compounds, and the pneumatic exploſions; meaning thoſe which are produced by the air ruſhing into a partial vacuum, by the diſcharge of air-guns and the like.

Of all theſe kinds of exploſions we ſhall now briefly treat, not in the order in which they have been enumerated, as this would prove a uſeleſs formality; but in a manner which may be more likely to elucidate the moſt intereſting part of the ſubject; and this undoubtedly is the ſtupendous force with which effects, in great variety, are produced in certain exploſions.

The firſt thing that ſtrikes the obſerver is the ſudden and violent noiſe of an exploſion. It is hardly neceſſary to obſerve that this noiſe or report is owing to the intermediation of the air between our ears and the cauſe, whatever that may be, of the percuſſion which is given to the air. Without that intermediation, or without air, the report could not be heard. But it muſt be farther obſerved, that the mere introduction of ſomething into the ambient air is not the principal cauſe of the report. That effect principally depends upon the ſudden replacing or collapſing of the air, after its having been removed or rarefied in any particular place. So that in order to account for the immediate cauſe of the noiſe in an exploſion, we muſt look out for ſomething which after having been introduced into the atmoſphere, whether ſlowly or quickly, is afterwards *ſuddenly* withdrawn or contracted. A few examples will eaſily illuſtrate this obſervation.

Take a common ſyringe, ſtop the aperture of it, then draw the piſton entirely out of its other extremity, and at that moment a report is heard, which is occaſioned by the replacing of the air within the ſyringe; for in drawing the piſton out of it, the air within the cavity of the ſyringe is rarefied, *viz.* a partial vacuum is formed, but as ſoon as the piſton is quite out, the air of the atmoſphere ſuddenly ruſhes in to ſupply that deficiency, and produces the noiſe or the report.

There is an experiment commonly ſhewn with the air-pump, and a glaſs veſſel open at both ends. To one of the apertures of the glaſs veſſel a wet piece of bladder is tied, and is ſuffered to become dry. The other aperture of the glaſs veſſel is then placed upon the plate of the air-pump. This done, the air is extracted by working the pump, by which means the glaſs veſſel covered over with the bladder is partially exhauſted, and of courſe the preſſure of the atmoſphere is in great meaſure removed from the under ſurface of the piece of bladder. The atmoſphere, then preſſing on the upper part of the bladder, and not being counteracted from below, diſtends the bladder towards the cavity of the veſſel, and at laſt breaks it with a conſiderable exploſion. The reaſon of which noiſe is the ſudden ruſhing in of the air.

An air-gun, when diſcharged, produces a trifling noiſe, the reaſon of which is, that after the expulſion of the condenſed air from the inſide of the inſtrument, which is impelled againſt the ambient air, there is no collapſion of the latter; for the condenſed air, on coming out of its confinement, expands itſelf to the tenſion of the ambient air, and remains in that ſtate; *viz.* without any ſubſequent contraction.

There are little glaſs balls, containing a ſmall quantity of water, which are made and ſold for diverting experiments, under the name of *glaſs granades.* A ball of this kind is nothing more than a diminutive glaſs bottle partially filled with water, and having a longiſh neck or tail, hermetically ſealed. One of theſe little bottles is ſtuck with its tail into the tallow or wax of a burning candle, and ſo that the little ball may be in the flame of the candle. In this ſituation the heat of the flame converts part of the fluid within the ball into vapour, and when the elaſticity of this vapour is ſufficient to overcome the reſiſtance of the glaſs the ball breaks, and produces a ſmart exploſion. The reaſon of which is, that the condenſed vapour, on coming out of the glaſs, diſplaces a conſiderable quantity of air, but being inſtantly cooled, it contracts, and the air collapſes.

A muſket loaded with gunpowder, on being fired off, produces a ſtrong exploſion. Now the difference between the diſcharge of ſuch a muſket and that of an air-gun is, that though in both an elaſtic fluid is diſcharged; yet in the muſket the elaſtic fluid contracts immediately after its coming into contact with the external air: but with the air-gun, the elaſtic fluid which iſſues out of it does not contract after its expulſion; hence the report is incomparably louder with the former than with the latter.

An electric ſpark, eſpecially in the diſcharge of a Leyden phial or battery, is accompanied with a ſmart report, in conſequence of its ſuddenly diſplacing the air from the ſpot in which it explodes; and of the ſubſequent collapſing of the air. And that the electric ſpark really diſplaces the air, is eaſily ſhewn by means of an electrical inſtrument, called "Kinnerſley's electrical air thermometer." In this inſtrument the ſpark is taken into a cloſe glaſs veſſel, which by an annexed narrow tube, partially filled with a liquor, indicates the rarefaction or diſplacing of the air within the veſſel. With this apparatus, whenever a ſpark or diſcharge of an electric jar is taken within the cloſe veſſel, the riſing and falling of the liquor within the annexed tube ſhews that the air is ſuddenly diſplaced, and is likewiſe heated in ſome degree; for the liquor riſes ſuddenly to a certain degree; and as ſuddenly deſcends, not quite to its former ſtation, but to a place a little above it, from which afterwards it deſcends gently to its original ſtation.

From theſe facts, and from a vaſt many more which might here be deſcribed, it clearly appears that the ſudden introduction of ſomething into the ambient air produces little noiſe; but that the noiſe of an exploſion is moſtly due to the collapſing of the air, which takes place in conſequence of the inſtantaneous contraction of that which has been introduced in it. The noiſe, *ceteris paribus*, is more or leſs loud in proportion as a greater or leſſer quantity of air is diſplaced and replaced, and likewiſe in proportion to the quickneſs of that operation.

When more reports than one are heard; theſe are produced either by an equal number of exploſions, or by a reverberation, *viz.* by an echo.

The air thus agitated conveys the ſound of an exploſion, or propagates its own vibrations, to immenſe diſtances. The firing of heavy ordnance has been ſometimes heard at the diſtance of 50 or 60, and even more miles. The exploſions of volcanoes, or thoſe which accompany earthquakes, have often been perceived at diſtances much more conſiderable; but with reſpect to the extent of this kind of communication, rate of moving, &c. the reader is referred to the article SOUND, *propagation of*, and HEARING. We ſhall, however, in this place, briefly mention an effect of this kind of violent aerial vibration: which it might be wiſhed that ſuch perſons as are opportunely ſituated, would examine with particular attention. The phenomenon is, that the exploſion of cannons, and eſpecially of powder magazines, or powder mills, renders the air conſiderably electrified, and that it electrifies the glaſſes of windows.

After the noiſe, or the report, the next ſtep is to inquire into the cauſe or cauſes which produce it: *viz.* into the nature of the elaſtic fluid which, in coming out of any confinement, diſplaces the circumambient air, and then ſuddenly gives way to it. Until very lately the immediate cauſe of moſt exploſions was principally attributed to the generation or extrication of permanently elaſtic fluids, *viz.* gaſes; and this is undoubtedly true in a great many caſes; but upon a cloſer examination of the concomitant particulars, the expulſion of theſe elaſtic fluids, even in a ſtate of incandeſcence, was found inadequate to the effects that were experienced in a variety of caſes; hence philoſophers began to look out for ſome other agent more active; and though the force of ſteam was known to be concerned in ſome kinds of exploſions; yet it muſt be acknowledged, that we are indebted to count Rumford for a maſterly examination of this particular point; for which purpoſe he inſtituted a long and laborious ſeries of well contrived experiments. His account at large under the title of "Experiments to determine the Force of fired Gunpowder," is contained in the Phil. Tranſ. for the year 1797, and from that account we ſhall extract ſuch particulars as may ſeem ſufficiently to illuſtrate this important part of the ſubject of exploſions. We call it important, becauſe it is the particular from which the cauſes of natural exploſions, ſuch as of volcanoes, earthquakes, &c. may be obviouſly manifeſted.

Count Rumford juſtly ſays, "The exploſion of gunpowder is certainly one of the moſt ſurpriſing phenomena we are acquainted with, and I am perſuaded it would much oftener have been the ſubject of the inveſtigations of ſpeculative philoſophers, as well as of profeſſional men, in this age of inquiry, were it not for the danger attending the experiments; but the force of gunpowder is ſo great, and its effects ſo ſudden and ſo terrible, that, notwithſtanding all the precautions poſſible, there is ever a conſiderable degree of danger attending the management of it."

Several able philoſophers had, at different times, endeavoured to determine the force of it. "But," count Rumford ſays, "the great deſideratum, the real meaſure of the initial expanſive force of inflamed gunpowder, ſo far from being known, has hitherto been rather gueſſed at than determined; and no argument can be more convincing to ſhew our total ignorance upon that ſubject, than the difference in the opinions of the greateſt mathematicians of the age, who have undertaken its inveſtigation."

The ingenious Mr. Robins thought, that the force of the elaſtic fluid, which is generated in the combuſtion of gunpowder, is 1000 times greater than the mean preſſure of the atmoſphere. Mr. D. Bernoulli reckoned it equal to 10,000 times that preſſure.

Count Rumford, in one of his firſt experiments, confined gunpowder in a ſtrong iron tube, and fired it by heating part of the tube, or rather of an appendage that had been fixed to it. This was done with a view of confining the elaſtic fluid, that was generated in the combuſtion. "The reſult," he ſays, "of this experiment fully anſwered my expectations. The generated elaſtic fluid was ſo completely confined, that no part of it could make its eſcape. The report of the exploſion was ſo very feeble, as hardly to be audible: indeed it did not by any means deſerve the name of a report, and certainly could not have been heard at the diſtance of twenty paces; it reſembled the noiſe which is occaſioned by the breaking of a very ſmall glaſs tube."

And farther on, he ſays, "It has generally been believed, after Mr. Robins, that the force of fired gunpowder conſiſts in the action of a permanently elaſtic fluid, ſimilar in many reſpects to common atmoſpheric air: which being generated from the powder in combuſtion, in great abundance, and being, moreover, in a very compreſſed ſtate, and its elaſticity being much augmented by the heat, (which is likewiſe generated in the combuſtion,) it eſcapes with great violence, by every avenue; and produces that loud report, and all thoſe terrible effects which attend the exploſion of gunpowder.

"But though this theory is very plauſible, and ſeems upon a curſory view of the ſubject to account in a ſatisfactory manner for all the phenomena, yet a more careful examination will ſhew it to be defective. There is no doubt but the permanently elaſtic fluid generated in the combuſtion of gunpowder, *aſſiſts* in producing thoſe effects which reſult from its exploſion; but it will be found, I believe, upon aſcertaining the real expanſive force of fired gunpowder, that this cauſe, alone, is quite inadequate to the effects actually produced: and that, therefore, the agency of ſome other power muſt neceſſarily be called in to its aſſiſtance."

This author then proceeds to deſcribe a variety of experiments and calculations which prove, beyond a doubt, that the above-mentioned theory is inſufficient to account for the effects which are produced by the inflammation of gunpowder; for he computes, in the ampleſt manner poſſible, the force of the gas which is generated even in the heat of red-hot iron, by which elevation of temperature air is known to be expanded not much above four times its ordinary bulk. He endeavoured to meaſure the force in queſtion by the lifting up of a very great weight, and his ingenious experiments were attended with reſults ſufficiently ſatisfactory; but we muſt refer the reader to the above-mentioned paper itſelf for the detail of theſe intereſting particulars; and we muſt here only add an abridgment of the latter part of the account, which more immediately relates to the principal object of our preſent enquiry.

"I will finiſh," the Count ſays, "this paper by a computation, which will ſhew that the force of the elaſtic fluid generated in the combuſtion of gunpowder, enormous as it is, may be ſatisfactorily accounted for upon the ſuppoſition that its force depends *ſolely* on the elaſticity of watery vapour or ſteam.

"It has been ſhewn by a variety of experiments made in England, and in other countries, that the elaſticity of ſteam is redoubled by every addition of temperature equal to 30 degrees of Fahrenheit's thermometer.

"Suppoſing now a cavity of any dimenſions (equal in capacity to one cubic inch for inſtance) to be filled with gunpowder, and that on the combuſtion of the powder, and in conſequence of it, this ſpace is filled with ſteam (and I ſhall preſently ſhew that the water exiſting in the powder *as water* is abundantly ſufficient for generating this ſteam); if we know the heat communicated to this ſteam in the combuſtion of powder, we can compute the elaſticity it acquires by being ſo heated.

"Now it is certain that the heat generated in the combuſtion of gunpowder cannot poſſibly be leſs than that of red-hot iron. It is probably much greater, but we will ſuppoſe it to be only equal to 1000 degrees of Fahrenheit's ſcale, or ſomething leſs than iron viſibly red-hot in day light."

"As the elaſtic force of ſteam is juſt equal to the mean preſſure of the atmoſphere, when its temperature is equal to that of boiling water, or 212° of Fahrenheit's thermometer, and as its elaſticity is doubled by every addition of temperature equal to 30 degrees of the ſame ſcale, with the heat of $212° + 30° = 242°$ its elaſticity will be equal to the preſſure of two atmoſpheres; at the temperature of $242° + 30° = 272°$ it will be equal to four atmoſpheres, &c.

"Following up our computations on the principles aſſumed, (and they are founded on the moſt incontrovertible experiments,) we ſhall find that at $692° + 30° = 722°$, the elaſticity will be equal to the preſſure of 131,072 atmoſpheres, which is 130 times greater than the elaſtic force aſſigned by Mr. Robins to the fluid generated in the combuſtion of gunpowder; and about *one-ſixth* part greater than my experiments indicated it to be.

"But even here the heat is ſtill much below that which is moſt undoubtedly generated in the combuſtion of gunpowder. That the elaſticity of ſteam would actually be increaſed by heat in the ratio here aſſumed, can hardly be doubted; it has abſolutely been found to increaſe in this ratio in all the changes of temperature between the point of boiling water, (I may even ſay of freezing water,) and that of 280° of Fahrenheit's ſcale, and there does not appear to be any reaſon why the ſame law ſhould not hold in higher temperatures.

"A doubt might poſſibly ariſe with reſpect to the exiſtence of a ſufficient quantity of water in gunpowder, to fill the ſpace in which the powder is fired, with ſteam, at the moment of the exploſion, but this doubt may eaſily be removed.

"The beſt gunpowder, ſuch as was uſed in my experiments, is compoſed of 70 parts (in weight) of nitre, 18 parts of ſulphur, and 16 parts of charcoal; hence 100 parts of this powder contain $67\frac{3}{10}$ parts of nitre, $17\frac{3}{10}$ parts of ſulphur, and of charcoal $15\frac{4}{10}$ parts.

"Mr. Kirwan has ſhewn that in 100 parts of nitre there are ſeven parts of water of cryſtallization; conſequently in 100 parts of gunpowder, as it contains $67\frac{3}{10}$ parts of nitre, there muſt be $4\frac{711}{1000}$ parts of water.

"Now as one cubic inch of gunpowder, when the powder is well ſhaken together, weighs exactly as much as one cubic inch of water at the temperature of 55° F. namely 253,175 grains troy; a cubic inch of gunpowder in its drieſt ſtate muſt contain at leaſt $10\frac{927}{1000}$ grains of water;

for it is 100 to 4,711, as 253,175 to 10,927. But beſides the water of cryſtallization which exiſts in the nitre, there is always a conſiderable quantity of water in gunpowder, in that ſtate in which it makes bodies damp or moiſt. Charcoal expoſed to the air has been found to abſorb nearly $\frac{1}{8}$th of its weight of water, and by experiments I have made on gunpowder, by aſcertaining its loſs of weight on being much dried, and its acquiring this loſt weight again on being expoſed to the air, I have reaſon to think that the power of the charcoal, which enters into the compoſition of gunpowder, to abſorb water, remains unimpaired, and that it actually retains as much water in that ſtate as it would retain were it not mixed with the nitre and the ſulphur.

"As there are 15$\frac{4}{10}$ parts of charcoal in 100 parts of gunpowder, in one cubic inch of gunpowder, (= 253,175 grains troy,) there muſt be 38,989 grains of charcoal; and if we ſuppoſe $\frac{1}{8}$th of the apparent weight of this charcoal to be water, this will give 4,873 grains in weight for the water, which exiſts in the form of moiſture in one cubic inch of gunpowder.

"If now we compute the quantity of water which would be ſufficient, when reduced to ſteam under the mean preſſure of the atmoſphere, to fill a ſpace equal in capacity to one cubic inch, we ſhall find that either that contained in the nitre which enters into the compoſition of one cubic inch of gunpowder, as water of cryſtallization, or even that ſmall quantity which exiſts in the powder in the ſtate of moiſture, will be much more than ſufficient for that purpoſe.

"Though the denſity of ſteam has not been determined with that degree of preciſion that could be wiſhed, yet it is quite certain that it cannot be leſs than 2000 times rarer than water, when both are at the temperature of 212°. Some have ſuppoſed it to be more than 10,000 times rarer than water, and experiments have been made which ſeem to render this opinion not improbable; but we will take its denſity at the higheſt poſſible eſtimation, and ſuppoſe it to be only 2000 times rarer than water. As one cubic inch of water weighs 253,175 grains, the water contained in one cubic inch of ſteam at the temperature of 212° will be $\frac{1}{2000}$dth part of 253,175 grains, or 0.12659 of a grain.

"But we have ſeen that one cubic inch of gunpowder contains 10,927 grains of water of cryſtallization, and 4,873 grains in a ſtate of moiſture; conſequently the quantity of water of cryſtallization in gunpowder is 86 times greater, and the quantity which exiſts in it in a ſtate of moiſture, is 38 times greater than that which would be required to form a quantity of ſteam ſufficient to fill completely the ſpace occupied by the powder.

"Hence we may venture to conclude, that the quantity of water actually exiſting in gunpowder is much more than ſufficient to generate all the ſteam that would be neceſſary to account for the force diſplayed in the combuſtion of gunpowder, (ſuppoſing that force to depend ſolely on the action of ſteam,) even though no water ſhould be generated in the combuſtion of gunpowder. It is even very probable that there is more of it than is wanted, and that the force of gunpowder would be ſtill greater, could the quantity of water it contains be diminiſhed.

"From this computation it would appear that the difficulty is not to account for the force actually exerted by fired gunpowder, but to explain the reaſon why it does not exert a much greater force."

Beſides the common gunpowder, there are ſeveral other chemical compoſitions which are capable of exploding with greater or leſs violence; and the moſt remarkable of theſe compoſitions are, the gunpowder formed with the ſuperoxygenated muriate of ſoda, inſtead of nitre; that preparation of gold which, from its remarkable property, is called fulminating gold; the fulminating ſilver, Howard's mercurial powder, the common fulminating powder, which conſiſts of nitre, potaſh, and ſulphur, &c. The exploſions of almoſt every one of theſe chemical compoſitions is louder than the exploſion of an equal quantity of the common gunpowder; yet when confined in a barrel or other fit inſtrument, few of theſe compoſitions exert a force, or produce an effect equal to that of gunpowder. This, which at firſt ſight may appear to be an inexplicable paradox, will be eaſily underſtood by conſidering, that the ſmartneſs of the report depends in great meaſure on the quickneſs of the inflammation or exploſion; whereas the force of the exploſion is moſtly proportional to the quantity of elaſtic fluid, be it gas or vapour, which is generated, and that the abovementioned chemical mixtures explode quicker than common gunpowder, may be eaſily proved. Let, for inſtance, two trains of equal length be formed upon a ſtone pavement; *viz.* one with the common gunpowder, and another with Howard's mercurial powder, and let one extremity of each train come into mutual contact; ſo that by applying a red-hot iron to that point, both trains may be fired at the ſame time. It will be found that the train of mercurial powder goes off viſibly much quicker than that of gunpowder; for when the former is entirely conſumed, the fire of the latter will hardly have proceeded half way of the whole train.

The exploſion of the gunpowder made with the ſuperoxygenated muriate of ſoda, and Howard's mercurial powder, exert an immenſe force when fired in barrels or other like veſſels. Fulminating gold and fulminating ſilver explode very readily, eſpecially the latter, which, when once prepared, can no longer be touched; for it will explode, not only when heated a few degrees above the temperature of the atmoſphere, but even when touched with any ſolid body. Yet when either of theſe preparations is confined in a barrel or other like inſtrument, and is inflamed, the force which it exerts is by no means equal to that which one who has heard the noiſe of their exploſions would be led to expect. It is worthy of remark, that, upon the whole, no other compoſition hitherto diſcovered has been found preferable to the common gunpowder, for muſkets, cannons, and other inſtruments of the like nature. Moſt of theſe preparations are conſiderably more expenſive than the common gunpowder; ſome of them are not nearly ſo manageable as the gunpowder, for they will explode by the leaſt touch or grinding, even by the friction of the ſtopple into the neck of the veſſel that contains them; but the principal fault is that very property by which they might be expected to have a ſuperior power; namely, the quickneſs of their exploſion.

There is a certain time requiſite for the motion of the wadding and bullet from the lower part to the muzzle of a gun, and the gradual inflammation of the gunpowder, when uſed in proportionate quantity, ſeems to correſpond with that gradual movement of the bullet, wadding, &c. When the exploding compoſition goes off much quicker than the common gunpowder, that force which is exerted ſpherically all round, and quicker than the time during which the wadding, &c. can get along the cavity of the barrel, frequently breaks the barrel, and endangers the byſtanders. We cannot illuſtrate this effect better than by mentioning the common and well-known obſervation, that though an open door may be ſhut by a gentle application of a child's hand, yet if you point a gun, and fire a bullet at it, the latter will make a hole through it without ſhutting, or cloſing it in the leaſt.

Speaking of the force of exploſions, it may naturally be required that we ſhould treat of the force and effects of electrical exploſions. But as the nature of ſuch exploſions cannot be properly underſtood without other particulars relative to the ſubject of electricity, their force and effects will be found deſcribed under the articles which belong to that extenſive ſubject; ſuch as Electric *Sparks*, Leyden Phial, Fire *Balls*, Lightning, &c.

It is in a manner ſimilar to the effects of gunpowder, that water projected upon red-hot or fuſed metal, occaſions a moſt powerful, and moſt dangerous exploſion. In both caſes the water is inſtantly reduced into ſteam, at a high temperature, conſequently of very high elaſticity; hence the force which is exerted is often prodigiouſly great; and there are inſtances recorded of whole founderies having been inſtantly demoliſhed, in conſequence of ſome perſons having inadvertently ſpit upon the liquid metal. If a ſmall quantity of water be poured upon red-hot charcoal, or red-hot glaſs, a hiſſing noiſe is heard; the part which is touched by the water loſes its redneſs, and nothing elſe remarkable takes place, becauſe the above-mentioned ſubſtances are bad conductors of heat, and it is only that part which is touched by the water that communicates its heat to the water, and this is not ſufficient to convert the water ſuddenly into ſteam of very great elaſticity. But metallic bodies are the beſt conductors of heat, and fuſed copper is particularly ſo; hence, when a ſmall quantity of water happens to fall upon a large quantity of that metal, in a ſtate of fuſion, the heat from a great part of the metal ruſhes to the ſpot where the water is fallen, and inſtantly converts it into ſteam of high elaſticity.

The exploſion of a mixture of hydrogen and oxygen gaſes, or of hydrogen gas and common air, does likewiſe exert a conſiderable force, but not to be compared with that of gunpowder. Theſe gaſes, when inflamed, expand conſiderably, but inſtantly after, they contract into an exceedingly narrow compaſs, which occaſions the report; for, by the combuſtion, they are converted principally into water, the bulk of which is leſs than the ten or twenty thouſandth part of the original bulk of the gaſes.

The laſt kind of exploſion we ſhall take notice of, is produced not by the generation or contraction of an elaſtic fluid, but by a ſort of mechanical derangement. Thoſe lumps of glaſs with a long tail, or prolongation, which are well known by the name of Glaſs Tears, or Prince Rupert's Drops, are an inſtance of this kind. If one of theſe drops be held in the hand, and part of the tail is broke, a ſmart kind of exploſion is heard, and the whole is inſtantly converted into powder. In order to underſtand the cauſe of this phenomenon, it is in the firſt place neceſſary to conſider how theſe drops are formed. For this purpoſe the glaſs manufacturers take a quantity of the fuſed glaſs, (about half an ounce of it, and green bottle glaſs is the fitteſt for it,) and drop it in that ſtate of incandeſcence into cold water; the conſequence of which is, that the external part of the lump of glaſs is cooled and rendered ſolid long before the internal part of it. Then when the internal part is cooled, and of courſe contracts its dimenſions, the external part being already cooled and ſettled, cannot follow it, ſo that it remains in a ſtate of ſuſpenſion ſomewhat like an arch; hence, when part of the lump is broken, the key-ſtone, as it were, of the arch, is removed, and the whole aſſemblage of particles is deranged. See Glass *Tears*, for a more detailed explanation of theſe their properties.

Several other ſubſtances explode and are broken upon analogous principles. Such are glaſs veſſels made for different purpoſes, and eſpecially for electrical machines; alſo large caſt-metal veſſels ſometimes ſpontaneouſly explode and break in the act of cooling. Sir William Hamilton mentions certain volcanic bodies, which he calls *volcanic bombs*, that explode probably on the ſame principle. They were large pieces of lava, which burſt in pieces like bombs as they fell to the ground. Theſe were obſerved in the great eruption of mount Veſuvius, which took place in the year 1779. The cauſe of volcanic exploſions, as well as of thoſe which accompany or precede earthquakes, is moſtly attributed to the action of ſteam; but theſe kinds of exploſions will be found particularly examined under the articles Earthquake and Volcano.

The uſe to which certain exploſions are applied is ſo well known as not to require any particular deſcription. Every body knows the various uſes of ſhooting with gunpowder, eſpecially in military affairs. The blaſting or breaking of rocks, by means of the exploſion of gunpowder, is likewiſe well known. But theſe uſes, together with all the particulars that relate to them, are often mentioned in various other articles of this Cyclopædia; ſuch as Gunnery, Mining, Shooting, &c.

EXPOLITION, in *Rhetoric*, a figure whereby we explain the ſame thing in different phraſes and expreſſions, in order to ſhew it more fully.

Expolition was the favourite figure of Balzac.

EXPONAS Venditioni. See Venditioni.

EXPONENT, from *expono*, *I expreſs*, in *Arithmetic*. Exponent of a power denotes the number which expreſſes the degree of the power, or which ſhews how often a given power is to be divided by its root before it be brought down to unity.

Thus, the exponent or index of a ſquare number is 2; of a cube, 3; the ſquare being a power of the ſecond degree; the cube of a third, &c.

Exponents are commonly written above, and ſomewhat towards the right-hand of the number or quantity whoſe power they expreſs. Thus, 3^5, a^5, ſignify the fifth power of 3, and of a. See Power.

Exponent is alſo uſed in the ſame ſenſe with index or logarithm.

Thus a ſeries of numbers in arithmetical progreſſion being placed under another ſeries in geometrical progreſſion, are called the exponents, indices, or logarithms thereof. *E. gr.* in the two progreſſions,

Geom. 1, 2, 4, 8, 16, 32, 64, 128, 256, 512
Arith. 0, 1, 2, 3, 4, 5, 6, 7, 8, 9

0 is the exponent, index, or logarithm of the firſt term 1; 5 that of the ſixth, 32, &c.

Hence, unity is to the exponent of a power as the logarithm of the root to the logarithm of its power; conſequently, the logarithm of the power is had by multiplying the logarithm of the root by its exponent; and the logarithm of the root is had by dividing the logarithm of the power by its exponent.

Exponent *of a ratio*, is the quotient ariſing upon dividing the antecedent by the conſequent.

Thus, in the ratio 3 to 2 the exponent is $1\frac{1}{2}$, and the exponent of the ratio 2 to 3 is $\frac{2}{3}$. See Ratio.

Hence, 1. If the conſequent be unity, the antecedent is the exponent of the ratio. Thus, *e. gr.* the exponent of the

the ratio 4 to 1 is 4; and again, the exponent of a ratio is to unity as the antecedent to the conſequent.

2. Since in a rational ratio the exponent of a ratio is had by dividing a rational number by another rational, the exponent of a rational ratio is a rational number.

EXPONENTIAL Calculus, *Calculus exponentialis*, is a method of differencing exponential quantities, and of ſumming up the differences of exponentials. See Calculus.

Exponential *curve* is that which is defined by an exponential equation.

Exponential curves partake both of the nature of algebraic and tranſcendental ones; of the former, becauſe they conſiſt of a finite number of terms, though thoſe terms themſelves are indeterminate; and of the latter, becauſe they cannot be algebraically conſtructed, or repreſented by an algebraic equation. Thus $a y = x^2$ is the equation of an algebraic curve; $y = a^x$ is the equation of an exponential curve: this equation $y = a^x$ denotes that any ordinate y is to a conſtant ordinate aſſumed equal to 1, as a conſtant quantity a raiſed to a power whoſe exponent expreſſes the ratio of the abſciſs x to the line equal to 1 is to the line taken for unit or 1, raiſed to the ſame exponent. Let b repreſent the line = 1, and the equation $y = a^x$ (ſince $y : b :: a^{\frac{x}{b}} : b^{\frac{x}{b}}$), will become $\frac{y}{b} = \frac{a^{\frac{x}{b}}}{b^{\frac{x}{b}}}$. Note, $y = a^x$ is the equation of the logarithmic curve. See Logarithmic. See alſo Curve.

Exponential *equation*, is that wherein there is an exponential quantity. See Equation, &c.

Exponential *quantity*, is a power whoſe exponent is an indeterminate or variable quantity.

Exponential quantities are of ſeveral degrees and orders: when the exponent is a ſimple indeterminate quantity, it is called an exponential of the firſt or loweſt degree.

When the exponent itſelf is an exponential of the firſt degree, then the quantity is an exponential of the ſecond degree. Thus, z^y is an exponential of the firſt degree, becauſe the quantity y is a ſimple flowing quantity; but z^{y^x} is an exponential quantity of the ſecond degree; becauſe y^x is an exponential of the firſt degree; ſo alſo, $z^{y^{x^y}}$ is an exponential of the third degree, the exponent y^{x^y} being one of the ſecond; and univerſally, the exponential quantity of any degree has for its exponent, the exponential quantity of the degree next preceding it. See Bernouilli Oper. tom. i. p. 182, &c.

EXPORTATION, in *Commerce*, the act of ſending commodities out of one country into another.

Exportation is a part of foreign commerce (ſee Commerce), diſtinguiſhed by the appellation *active*, or *ſelling part*, in oppoſition to *importation*, which is called the *paſſive*, or *buying part*. It is obſerved, as a general maxim, that commerce, when active, muſt produce a flow of riches, the balance being received in money; whereas, if it be paſſive, treaſures will be exhauſted, as the balance of trade muſt continually be made good out of the remaining coin. Hence, plenty of money in any place implies, that the quantity of goods exported far exceeds that of goods imported; and wherever money is ſcarce, it may be concluded that greater quantities of goods have been imported than exported. See Exchange.

It has been a principal object of commercial policy in almoſt every country, to encourage exportation, with the exception of a few articles; that of manufactured goods has been promoted with a view of encouraging the internal induſtry of the country, and that of foreign produce, as a means of drawing wealth from other countries by the profits of the carrying trade. The exceſs of the value of goods exported beyond that of the imports has uſually been conſidered as a criterion of the profits which a country derives from foreign trade; but this is a fallacious mode of determining this important point, becauſe advantageous foreign trade might long exiſt, even if the imports conſtantly exceeded the value of the exports. The laws in force relating to exportation conſiſt principally of prohibitory or reſtrictive regulations concerning bullion, corn, wool, machinery, and tools uſed in various branches of the manufactures, the exportation of which, it is thought, might diminiſh the neceſſary ſupply of proviſions for the conſumption of the country, or enable foreigners to rival valuable branches of its manufactures. The acts relative to the exportation of wool, prohibit the exportation, not only of the commodity itſelf, but alſo of live ſheep, rams, or lambs, from Great Britain, Ireland, Jerſey, Guernſey, Alderney, Sark, or Man, on penalty of the forfeiture thereof, and of the ſhips conveying them; alſo 3*l.* for every ſheep, &c. and three months' ſolitary impriſonment of the offender; for a ſecond offence, 5*l.* for every ſheep, &c. and ſix months' impriſonment; except wether ſheep for ſhips' uſe, put on board by licence of the port-officer of the cuſtoms. A limited quantity of wool, however, is allowed to be exported from the port of Southampton to Jerſey, Guernſey, Alderney, and Sark.

The duties on exportation, payable in Great Britain and Ireland, were formerly the principal branch of the revenue derived from foreign trade; but they are now of ſmall amount compared with the duties payable on goods brought into the country.

The *official* value of all exports from Great Britain, for three years ending the 5th of January 1809, was as follows:

		Britiſh produce and manufactures.	Foreign merchandize.
Year ending 5th Jan.	1807	£. 27,402,685	£. 9,124,499
- - -	1808	25,171,422	9,395,149
- - -	1809	26,692,288	7,863,207

The *actual* value of Britiſh produce and manufactures exported from Great Britain, agreeably to the prices current, and to the declarations of the exporters, was, in the year ending the 5th of January 1809, £. 40,881,871.

The official value of imports into Great Britain from Europe, Africa, and America, during the ſame periods, is as follows:

Year ending 5th January	1807	£. 25,085,136
- - - -	1808	25,453,149
- - - -	1809	23,784,516

The official value of imports into Great Britain from Eaſt India and China is as follows:

Year ending 5th January	1807	£. 3,746,771
- - - -	1808	3,401,509
- - - -	1809	not aſcertained.

The real value of Iriſh produce and manufactures exported from Ireland in the year ending the 5th of January 1809, computed at the average prices current, was £. 12,577,517 10*s.* 11*d.*

10*s.* 11*d.* See Customs, and Duty. See alſo Commerce.

Dr. Smith, in his "Nature and Cauſes of the Wealth of Nations," ſtates and explains the principles upon which the exportation trade is founded. When the produce of any particular branch of induſtry exceeds what the demand of the country requires, the ſurplus muſt be ſent abroad, and exchanged for ſomething for which there is a demand at home. Without ſuch exportation, a part of the productive labour of the country muſt ceaſe, and the value of its annual produce diminiſh. The land and labour of Great Britain produce generally more corn, woollens, and hard ware, beſides ſome other manufactures, than the demand of the home market requires. The ſurplus part of them muſt, therefore, be ſent abroad, and exchanged in the manner already mentioned. It is only by means of ſuch exportation, that this ſurplus can acquire a value ſufficient to compenſate the labour and expence of producing it. The neighbourhood of the ſea-coaſt, and the banks of all navigable rivers, are advantageous ſituations for induſtry, only becauſe they facilitate the exportation and exchange of ſuch ſurplus produce for ſomething elſe, which is more in demand there.

When the foreign goods, which are thus purchaſed with the ſurplus produce of domeſtic induſtry, exceed the demand of the home market, the ſurplus part of them muſt be ſent abroad again, and exchanged for ſomething more in demand at home. When the capital ſtock of any country is increaſed to ſuch a degree that it cannot be wholly employed in ſupplying the conſumption, and ſupporting the productive labour of that particular country, the ſurplus part of it naturally diſgorges into the carrying trade, and is employed in performing the ſame office to other countries. The carrying trade is the natural effect, and ſymptom of great national wealth; but it does not ſeem, ſays Dr. Smith, to be the natural cauſe of it. Holland had formerly the greateſt ſhare of the carrying trade of Europe, and in proportion to the extent of its land, and the number of its inhabitants, it was the richeſt country in Europe. England, now the richeſt country of Europe, has appropriated to itſelf the greateſt ſhare of this trade. This ingenious writer ſuggeſts, that, whether the capital, which carries this ſurplus produce abroad, be a foreign or a domeſtic one, is of very little importance. If the ſociety has not acquired ſufficient capital both to cultivate all its lands, and to manufacture in the completeſt manner the whole of its rude produce, there is even a conſiderable advantage derived from the exporting of that rude produce by a foreign capital, in order that the whole ſtock of the ſociety may be employed to more uſeful purpoſes.

Dr. Smith farther obſerves, in reference to this ſubject, that with a view of multiplying gold and ſilver, in which, it has been commonly ſuppoſed, the wealth of a country conſiſts, it neceſſarily became the great object of political economy to diminiſh, as much as poſſible, the importation of foreign goods for home conſumption, and to increaſe, as much as poſſible, the exportation of the produce of domeſtic induſtry: and, therefore, its two great engines for enriching the country have been reſtraints upon importation, and encouragement to exportation. The former were of two kinds, *viz.* reſtraints upon the importation of ſuch foreign goods for home conſumption as could be produced at home, from whatever country they were imported; and reſtraints upon the importations of goods of almoſt all kinds, from thoſe particular countries, with which the balance of trade was ſuppoſed to be diſadvantageous. Theſe different reſtraints conſiſted ſometimes in high duties, and ſometimes in abſolute prohibitions. Exportation was encouraged ſometimes by drawbacks, ſometimes by bounties, ſometimes by advantageous treaties of commerce, and ſometimes by the eſtabliſhment of colonies in diſtant countries. Thus it has been intended to increaſe the quantity of gold and ſilver in any country by turning the balance of trade in its favour. Our author has particularly examined what are likely to be the effects of theſe reſtraints and encouragements upon the annual produce of the induſtry of a country. According as they tend either to increaſe or diminiſh the value of this annual produce, they muſt evidently tend either to increaſe or diminiſh the real wealth and revenue of the country. See Exchange, Monopoly, and *Balance of* Trade. Of the encouragements to exportation above enumerated, thoſe which are called *Drawbacks* (ſee the article) ſeem to Dr. Smith to be the moſt reaſonable. Concerning the grant of bounties; ſee Bounty.

EXPOSING, the act of ſetting a thing to public view.

In the Romiſh church, the ſacrament is ſaid to be expoſed when it is ſhewn in public, uncovered, on feſtival days, and during the time of plenary indulgences.

Exposing is alſo uſed with a farther latitude; thus, we ſay it is prohibited to expoſe falſe and clipped money.

Such a houſe ſtands very high, and has a delicious proſpect; but it is expoſed to all the four winds. Such a city being on the frontiers, and not fortified, is expoſed to the inſults of every party of forces.

Exposing *of Children*, a barbarous cuſtom practiſed by moſt of the ancients excepting the Thebans, who had an expreſs law to the contrary, whereby it was made capital to expoſe children, ordaining at the ſame time that ſuch as were not in a condition to educate them, ſhould bring them to the magiſtrates, in order to be brought up at the public expence. (Ælian Hiſt. Var. l. ii. c. 7.) Among the other Greeks, when a child was born, it was laid on the ground; and if the father deſigned to educate his child, he immediately took it up; but if he forebore to do this, the child was carried away, and expoſed. Pitiſc. Lex. Ant. in voc. Expoſitio.

The Lacedæmonians, indeed, had a different cuſtom; for with them all new-born children were brought before certain tryers, who were ſome of the graveſt men in their own tribe, by whom the infants were carefully viewed; and if they were found luſty and well-favoured, they gave orders for their education, and allotted a certain proportion of land for their maintenance: but if weakly, or deformed, they ordered them to be caſt into a deep cavern in the earth, near the mountain Taygetus, as thinking it neither for the good of the children themſelves, nor for the public intereſt, that defective children ſhould be brought up. Plutarch takes notice of this law of Lycurgus, and paſſes no cenſure upon it.

Many perſons expoſed their children only becauſe they were not in a condition to educate them, having no intention that they ſhould periſh. It was the unhappy fate of daughters eſpecially to be thus treated, as requiring more charges to educate and ſettle them in the world than ſons.

The parents frequently tied jewels and rings to the children they expoſed, or any other thing whereby they might afterwards diſcover them, if Providence took care of their ſafety. Another deſign, in adorning theſe infants, was either to encourage ſuch as found them to nouriſh and educate them, if alive; or to give them human burial, if dead.

The places where it was uſual to expoſe children were ſuch as people frequented moſt. This was done in order that they might be found, and taken up by compaſſionate perſons who were in circumſtances to be at the expence of their education. With this intention the Egyptians and

Romans choſe the banks of rivers, and the Greeks the highways.

Dionyſius Halicarn. (Antiq. Rom. l. ii.) informs us, that Romulus obliged the citizens to bring up all their male children, and the eldeſt of the females. They were allowed therefore to deſtroy all their female children but the eldeſt. And even with regard to their male children, if they were deformed or monſtrous, he permitted the parents to expoſe them, after having ſhewn them to five of their neareſt neighbours. In Cicero's third book of laws, (cap. 8.) there is a paſſage, from which it has been concluded, that the law of Romulus, with regard to the expoſing and deſtroying of male children that were remarkably deformed, was confirmed by a conſtitution of the twelve tables. It appears, from a paſſage in Terence, that this inhuman cuſtom of expoſing and deſtroying children, eſpecially females, was not uncommon even among parents of the beſt character. Sentiments of this kind were publiſhed with applauſe on the Roman theatre: and we learn from Seneca (de Ira, l. i. c. 15.) that ſo late as in his time, it was uſual among the Romans to deſtroy weak and deformed children. "Portentoſos fœtus extinguimus: liberos quoque, ſi debiles monſtroſique editi ſunt, mergimus."

This unnatural practice was preſcribed and approved even by the more eminent philoſophers. Plato (Republ. l. v.) recommends it to be ordered by law that men or women, who are paſt the age of having ſtrong children, ſhould take care that their offspring, if they ſhould have any, ſhould not come to the birth, or ſee the light; or if that ſhould happen, that they ſhould expoſe them without nouriſhment. Ariſtotle (Politic. l. vii. c. 16.) expreſsly ſays, that it ſhould be a law not to bring up or nouriſh any child that is weak or maimed; and that when the law of the country forbids to expoſe infants, it is neceſſary to limit the number of thoſe who ſhould be begotten; and if any one begets children above the number limited by the laws, he adviſes to procure abortion before the fœtus has life and ſenſe. The practice that has long prevailed among the Chineſe, and that ſubſiſts among them even to this day, is well known.

EXPOSITION, the act of expoſing. See Exposing.

Exposition is likewiſe applied to the interpretation or explication of an author, or paſſage therein. See Exegesis.

Exposition *of deeds*, in *Law*, ſhall be favourable, according to the apparent intent; and be reaſonable, and equal, &c. Co. Litt. 313.

Exposition, *expoſitio*, in *Rhetoric*, is ſometimes uſed for diviſion. See Division; and ſee alſo Exergasia.

Exposition, in *Gardening*. See Exposure.

EXPOSITOR, or Expository, a title which ſome writers have given to a leſſer kind of dictionaries or vocabularies, ſerving to expound or explain the meaning of the obſcure or difficult words of a language.

It is alſo uſed in the ſame ſenſe with commentary and paraphraſe.

EX POST FACTO, in *Law*, denotes ſomething done after another thing that was committed before. An eſtate granted may be made good by matter ex poſt facto, that was not ſo at firſt, by election, &c.

EXPOSTULATION, Expostulatio, in *Rhetoric*, a complaint addreſſed to a perſon from whom we have received ſome injury. It varies according to circumſtances.

EXPOSURE, or Exposition, in *Gardening*, the aſpect or ſituation of a garden wall, building, or the like, with reſpect to the ſun, wind, &c.

There are four regular kinds of expoſures, *viz*, eaſt, weſt, north, and ſouth; but it muſt be obſerved that among gardeners theſe terms ſignify juſt the contrary to what they do among geographers.

The gardeners, in effect, do not give the names eaſt, weſt, &c. to the places where the ſun is, but to thoſe whereon he ſhines; and they conſider the manner wherein he ſhines, whether as to the whole garden, or ſome of its ſides.

If they find, that the ſun at his riſing, and during the firſt half of the day, continues to ſhine on one ſide of a garden or wall, they call that an eaſtern expoſure, or eaſt wall, &c. and if the ſun begin to ſhine later, or end ſooner, it is not a proper eaſtern expoſure.

For the ſame reaſon, they call the weſt the ſide the ſun ſhines on the latter half of the day; *i. e.* from noon to night; and accordingly, the ſouth, or ſouthern expoſure, is the place whereon he ſhines from about nine o'clock in the morning till night; or which, in the general, he ſhines longeſt on in the whole day; and the part he ſhines leaſt on is the north, or ſouthern expoſure, at what hour ſoever it begin or end, being uſually from eleven o'clock to one.

The eaſtern and ſouthern expoſures are, by common conſent of all gardeners, the two principal, and have a conſiderable advantage above the reſt. A weſt expoſure is not much amiſs; at leaſt, it is better than a northern one, which is the worſt of all: each has its inconveniences.

The eaſtern, commencing differently at different ſeaſons of the year, and ending about noon, ſubjects the trees, &c. to the N.E. winds, which wither the leaves and new ſhoots, blow down the fruit, &c. beſide that it has little benefit of rains, which come moſtly from the weſt. Yet does the reverend Mr. Laurence judge the eaſt better than the weſt-wall for all kinds of fruit; not that it has more hours of ſun, or that there are any peculiar virtues in the eaſtern rays, but becauſe the early rays of the ſun do ſooner take off the cold chilly dews of the night.

M. Gentil recommends the eaſtern expoſure as beſt for all kinds of peaches; adding, that they ripen ſooneſt, grow bigger, are better coloured, and of a finer taſte, than in any other: but Mr. Carpenter reſtrains the rule to the early and middle ſorts; for the backward, he rather chooſes a ſouthern, or ſouth-eaſt expoſure, which is beſt for all late fruits, becauſe the influence of the ſun is ſtrongeſt, and continues longeſt.

The weſtern, accounted from half an hour paſt eleven till ſun-ſet, is backwarder than an eaſtern one by eight or ten days; but it has this advantage, that it receives little damage from the froſts, which melt before the ſun comes to ſhine upon the fruit, and fall off like dew, without doing any prejudice; ſo that it may bear apricots, peaches, pears, and plums; but it is incommoded with north weſt winds in the ſpring, as alſo with the autumnal winds, which blow down a great quantity of fruit.

According to Mr. Miller, the beſt aſpect or expoſure for walls in England is the point to the eaſtward of the ſouth; becauſe thoſe will enjoy the benefit of the morning ſun, and be leſs expoſed to the weſt and ſouth-weſt winds, which are very injurious to fruits in England, than thoſe walls which are erected due ſouth; the next beſt expoſure is due ſouth, and the next to that ſouth-eaſt, which is preferable to the ſouth-weſt. Other walls, however, may be planted with fruit-trees that ſuit their ſeveral expoſures.

The northern expoſure is the leaſt favourable of any in England, as having very little benefit from the ſun even in the height of ſummer, therefore can be but of little uſe, whatever may have been advanced to the contrary. For although many ſorts of fruit-trees will thrive and produce fruit in ſuch poſitions, yet ſuch fruit can be of little worth, ſince they are deprived of the kindly warmth of the ſun to correct their crude juices, and render them well taſted and wholeſome. It is therefore to little purpoſe to plant fruit-trees againſt ſuch walls, except it be for fruit intended for baking, &c. in which caſe the fire will ripen and render thoſe juices wholeſome which could not be performed while growing.

In ſuch ſituations, morelli cherries for preſerving may be planted, and white and red currants to come late, after thoſe which were more expoſed to the ſun are gone; and if the ſoil be warm and dry, ſome ſorts of ſummer pears will do tolerably well on ſuch an expoſure, and will continue longer in eating than if they were expoſed to the ſun. But winter pears ſhould by no means be planted in ſuch an aſpect, as has been practiſed by many ignorant perſons, if we find that the beſt ſouth walls in ſome bad years are barely warm enough to ripen them. Duke cherries planted againſt walls expoſed to the north will ripen much later in the ſeaſon; and if the ſoil be warm, will be well flavoured, and continue a month later than others. Miller.

The ſouthern expoſure, accounted from about nine till four, is recommended for peaches, pears, grapes, and plums.

EXPRESS, ſomething that is preciſe in formal terms, or for ſome particular deſign. I told him as much in expreſs terms; he gave me a commiſſion expreſs; he had expreſs orders; a courier was diſpatched expreſs.

We alſo ſay, ſomewhat abuſively, to ſend an expreſs, meaning a courier.

Express *Condition*, *Contract*, *Malice*, and *Warranty*. See the ſubſtantives.

EXPRESSED Oils, are ſuch as are procured from bodies only by preſſing; as the oils of olives, almonds, and the like. See Oil.

Expressed *ſpecies*. See Species.

EXPRESSION, in *Algebra*, denotes the value of a quantity expreſſed or repreſented under an algebraic form: thus, if $x = \sqrt{a^2 + b^2}$, and *a* and *b* are known, the value of *x* is known. See Equation.

Expression, in *Chemiſtry*, *Pharmacy*, &c. the act of expreſſing out, or extracting the juices of oils or plants, fruits, or other matters, by ſqueezing, wringing, or preſſing them in a preſs. This is one of the three modes of obtaining them; the other two being *infuſion* and *decoction*, which ſee. The hard fruits ſhould be well bruiſed, and herbs moderately bruiſed, before expreſſion. They are then to be incloſed in a hair or other bag, and preſſed between wooden plates in the common ſcrew preſs, till the juice ceaſes to run. The expreſſion of oils is performed nearly in the ſame manner as that of juices, by means of iron plates, or the apparatus of an oil-mill, adapted to this purpoſe. The inſipid oils of all unctuous ſeeds are obtained uninjured by this operation, if performed without the aid of heat, which, though it may promote the extraction of the oil, gives it an ungrateful flavour. The oils expreſſed from aromatic ſubſtances generally carry with them a portion of their eſſential oil.

Expression, in *Muſic*, is a quality by which a muſician manifeſts his feeling, and executes with energy all the ideas with which he ought to impreſs the hearer, and all the ſentiments which the compoſer intended to expreſs. There is an expreſſion in compoſition as well as in its execution, and it is by their concurrence that the moſt pleaſing and agreeable effect reſults.

To give an expreſſion to his works, a compoſer ought to ſeize and compare all the relations which can be found between the features of his object, and the productions of his art; in a muſical drama, he ought to know and feel the peculiar caſt of all the characters, in order ſeverally to exhibit them exactly as delineated by the poet; for as a good painter does not throw the ſame light on every figure, neither will the able muſician give the ſame energy to all the ſentiments, nor the ſame force to every figure, but will put each part in its true place, leſs to give it weight, individually, than to contribute to the effect of the whole.

After having well conſidered what a character has to ſay, he meditates how he ſhall ſay it; and here begins the application of the precepts of his art, which is to find the particular language in which the actor would wiſh to make himſelf underſtood.

Melody, harmony, movement, choice of inſtruments and voices, are the elements of the muſical language; and melody, by its immediate connection with the grammatical and oratorical accent, is that which gives a character to all the reſt. So that it is conſtantly from melody that the principal expreſſion ſhould be derived, as well in inſtrumental as vocal muſic.

What a compoſer therefore has to expreſs by melody is tone of voice, with which the ſentiments can beſt be rendered; and care ſhould be taken not to mimic that of theatrical declamation, which is in itſelf only an imitation, but the voice of nature ſpeaking without affectation and without art.

The compoſer will therefore at firſt ſeek a kind of melody which ſhall furniſh muſical inflections the moſt conſonant to the ſenſe of the words, always lowering their expreſſion to the thought, and the thought to the interlocutor's ſtate of mind; for when we are ſtrongly affected, all that we ſay in a manner ſavours of the general ſentiments which govern us; and we never chide what we love in the ſame tones as we ſhould an indifferent perſon. Our ſpeech is differently accented according to the different paſſions by which we are agitated; ſometimes acute and vehement, ſometimes languid and monotonous, ſometimes varied and imperious, ſometimes ſmooth and tranquil in its inflections. Thence the muſician regulates the choice of keys which he uſes in his melody, and the different places in which he employs voice, keeping it down with ſmall intervals to expreſs the languor of ſorrow and dejection; and ſtraining it with acute ſounds in paſſion and grief; driving it rapidly through all the intervals of the diapaſon in the agitation of deſpair, or the turbulence of diſtracted paſſions. Above all it muſt be remembered, that the charms of muſic conſiſt not only in imitation, but in an agreeable imitation; and that the declamation (or recitative) itſelf to have its full effect, ſhould be ſubordinate to melody; ſo that there is no painting ſentiment without giving it this ſecret charm inſeparable from it, nor touch the heart without pleaſing the ear. And this is ſtill very conformable to nature, which gives to the tone of voice of perſons of ſenſibility, certain touching and delicious inflections, which thoſe who feel nothing never poſſeſſed. Never, therefore, miſtake rough and coarſe for expreſſive, nor harſhneſs for energy. Give not a hideous picture of the paſſion which you wiſh to paint, nor imitate the performers at the French opera, where the voice of paſſion reſembles a complaint of the colic, more than tranſports of love.

The natural pleaſure which reſults from harmony, augments in its turn the moral pleaſure of imitation, in uniting the agreeable ſenſations of chords to the expreſſion of the melody, upon the ſame principle as that juſt mentioned. But harmony does ſtill more; it enforces even the expreſſion in giving more truth and preciſion to melodious intervals; it animates their character, and exactly marks their place in the order of the modulation; it calls back the preceding, announces that which ought to follow, and thus connects the phraſes in the melody, as ideas are linked together by grammar in a diſcourſe. Harmony, regarded in this light, furniſhes the compoſer with powerful means of expreſſion, which eſcape him when he ſeeks expreſſion in harmony alone; for then, inſtead of animating the accent, he extinguiſhes it by his chords, and all the intervals, confounded in a continued crowd of combined ſounds, offer to the ear only a ſeries of fundamental chords, which have nothing touching or agreeable in their effect, and often not only ſuffocates the melody, but the ſenſe of the words. What then muſt the harmoniſt do to fortify the expreſſion of the melody, and give it more effect? He will carefully avoid covering the principal ſound in the combination of chords; he will render all the notes of the accompaniment ſubordinate to the vocal part; he will give relief and energy to it by the concurrence of other parts; he will enforce the effect of certain paſſages, by the chord of the ſharp 7th; he will diſguiſe others by ſuppoſition or ſuſpenſion, in making no proviſion for them in the baſe; he will gain ſtrong expreſſions by major diſcords, he will reſerve the minor, for tender ſentiments; ſometimes he will unite all his parts by ſmooth and flowing notes; ſometimes he will contraſt them with the melody by pointed notes; ſometimes he will fill the ear with full harmony, and ſometimes enforce the accent by the choice of a ſingle interval. He will render preſent and ſenſible the chain of modulation throughout, and will make the baſe and its harmony ſerve to determine the place of each paſſage in the key, in order that no interval or trait of melody ſhall be heard, without feeling at the ſame time its relation with the whole.

With reſpect to rhythm, formerly ſo powerful as to give force, variety, and ornament to poetical harmony; if modern languages leſs accentuated and leſs proſodic have loſt this charm, our muſic can ſubſtitute another more independent of ſpeech in the preciſion of meaſure, and in the combination of its proportions, whether moving together or ſeparately in each part.

Quantity in language is almoſt wholly loſt in notes of muſic; and the muſic, inſtead of ſpeaking with words, borrows, in ſome ſort, from the meaſure a language apart.

The force of the expreſſion conſiſts in this particular, in the uniting theſe two languages as much as poſſible together, in ſuch ſort, that if the meaſure and the rhythm ſpeak not in the ſame manner, they will at leaſt ſay the ſame things.

Chearfulneſs, which gives vivacity to all our movements, ought to do the ſame in muſical meaſures. Melancholy locks up the heart, relaxes all our motions, and the ſame languor is felt in the melodies which it dictates; but when grief is poignant, or great conflicts are paſſing in the mind, ſpeech is unequal; it moves alternately with the ſlowneſs of the ſpondee and the rapidity of the Pyrrhic, and ſometimes ſuddenly ſtops ſhort, as in accompanied recitative; it is on this account, that the moſt expreſſive muſic, or at leaſt the moſt paſſionate, is commonly that in which the times or portions of each bar, though equal in themſelves, are the moſt unequally divided; whereas the image of ſleep, of repoſe, of peace of mind, require ſmall exertion of voice, and are naturally painted with notes of equal length, which move neither quick nor ſlow.

There is one obſervation which the compoſer ought not to neglect, and which is, that the more ſtudied and extraneous is the harmony, the ſlower ſhould be the movement, in order that the mind may have leiſure to diſentangle the diſcords, and follow the rapid chain of modulation. Nothing but the laſt degree of fury can permit the union of rapid meaſures and harſh chords. When the head is diſtracted, and the actor, by violent agitation, ſeems not to know what he ſays, this energetic and terrible confuſion may be communicated to the mind of the ſpectator, and, in like manner, make him loſe his reaſon. But if the compoſer is not inflamed and ſublime, he will only be coarſe and cold; if he does not throw the audience into a delirium, he runs a great riſk of a failure: for he who loſes his reaſon is only mad in the eyes of thoſe who preſerve it, and inſanity is no longer intereſting.

Though the greateſt force of expreſſion is derived from the combination of ſounds, the quality of their tone is not indifferent in the effect. There are voices ſo ſtrong and ſonorous as to impoſe by their force; others thin, flexible, and fit for execution; others again ſo touching and delicate as to penetrate the heart by ſoothing and pathetic ſtrains. In general, treble voices and acute are fitteſt to expreſs tenderneſs and affection; baſes and baritones for intemperate paſſion and choler; but the Italians have baniſhed baſes from their ſerious operas, as a part, of which the melody is too rude and boiſterous for the heroic ſtyle, and have ſubſtituted in their ſtead tenors, of which the melody has the ſame character, with a more agreeable effect. They employ baſe voices in the groteſque and ridiculous parts of their comic operas with more propriety.

Inſtruments have alſo their peculiar expreſſions, proportioned to their quality of tone, force, and compaſs. The flute is tender, the hautbois cheerful, the trumpet military, the horn ſonorous, majeſtic, and proper for grand expreſſions. But there is no inſtrument of more varied expreſſion, and more univerſally uſeful, than the violin. This admirable inſtrument is the foundation of every orcheſtra, and can furniſh a great compoſer with all the effects which mean muſicians vainly ſeek in a multitude of different inſtruments. The compoſer ought to be acquainted with the finger-board of the violin, to conſider the ſhifts, and know how to write arpeggios, by diſtinguiſhing the open from the ſtopped ſtrings, and to chooſe and make uſe of keys according to the different characters they have upon that inſtrument.

It is in vain for the compoſer to attempt to animate his orcheſtra, if the ardour which ought to reign in it does not inflame the performers. The ſinger who only ſees notes in his part, is not qualified to ſeize the expreſſion of the compoſer, nor to give one of his own to what he ſings, if he has not well comprehended the ſenſe. He muſt underſtand what he reads before he can make it comprehended by others; and it is not enough to be poſſeſſed of general ſenſibility, if not particularly energetic in the language we ſpeak. Let him begin therefore by thoroughly underſtanding the character of the melody which he has to execute, its expreſſion of the words, the diſtinction of its phraſes, the accent which it has in itſelf, that which it requires in the voice of the ſinger, the energy which the compoſer has given to the poet, and that which in his turn he can give to the compoſer. Let him reſign his whole powers, then, to all the enthuſiaſm which theſe conſiderations ſhall have inſpired; he ſhould expreſs every thing as completely as if he were at once the poet, compoſer, actor, and ſinger, and he will then have all the animation which it is poſſible for him to give to the work which he has to execute.

In this manner he will naturally embelliſh with taſte and delicacy airs that are only elegant and graceful; with ſpirit and fire, ſuch as are animated and gay; with ſighs, the tender and pathetic; and with all the agitation of forte and piano, ſuch as are expreſſive of rage and fury. Whenever the muſical and oratorical accents are united (as in arie parlanti), wherever the time ſhall be ſtrongly marked, and ſerve as a guide to the accents of the melody; wherever the accompaniment and the voice ſhall ſo agree in their effects as to form only one melody, and the hearer, deceived, wholly attributes to the voice the paſſages which the orcheſtra embelliſhes ; and, finally, wherever ſober ornaments, judiciouſly applied, manifeſt the abilities and facility of the ſinger, without diſguiſing and injuring the melody, the expreſſion will be ſweet, agreeable, and animated ; the ear will be delighted, and the heart affected ; nature and art will at once concur in pleaſing the hearer, and there will reign ſuch a coincidence between the words and the muſic, that the whole will ſeem to proceed from one delicious language, which can ſay every thing, and always pleaſe.

This is more a diſſertation than an article of a dictionary, but theſe are the ſentiments of the citizen of Geneva, to moſt of which in muſic we readily ſubſcribe, as he is ever more reaſonable and conſiſtent in ſpeaking of that art than on any other ſubject. His views concerning dramatic muſic are always ſo ingenious, elevated, and refined, that we cannot reſiſt tranſlating him. Though we fear that the French, with all their preſent rage for Italian muſic and Italian expreſſion, will not adopt them ; and the Italians themſelves, in their moſt happy moments of conception, have been ſucceſsful from inſtinct and enthuſiaſm, more than precepts or reflection.

Expression, in *Oratory*, denotes the manner of delivering or conveying one man's ideas to another. Accordingly it denotes that felicity of diſcriminative energy in the reader, ſpeaker, or reciter, by which the characteriſtic beauties or peculiarities, whether of language, ſentiment, or paſſion, in a compoſition or oration, are forcibly and happily illuſtrated, and the various ſhades and tranſitions of ſtyle, ſignification, feeling, and alluſion, in ſuch compoſition or oration, are diſtinctly and intereſtingly marked. Expreſſion in this, as in every other art, is one of the chief conſtituents of excellence ; and contradiſtinguiſhes the elocutioniſt of taſte and genius, from the mere mechanical reader or declaimer. It depends chiefly upon that quickneſs and vitality of perception which may be regarded, in ſome degree, as an original gift of nature, and on that prompt and perfect ſympathy between the perceptive faculty and the executive organs, which it is the higheſt glory of art and practical exerciſe to produce.

Expression is more particularly uſed for the elocution, diction, and choice of words in a diſcourſe. See Elocution.

It is not enough that a poet or orator have fine thoughts, he muſt likewiſe have a happy expreſſion. Defects in the expreſſion ordinarily ariſe from defects in the imagination : abundance of the beauties of the ancient writers are annexed either to expreſſions which are peculiar to their language, or to relations, which, not being ſo familiar to us as to them, do not give us the ſame pleaſure.

Expression, *diverſifying of*, in *Rhetoric*. See Diversifying.

Expression, in *Painting*, principally conſiſts in the repreſentation of thoſe attitudes of the body, and variations of the countenance of men, which always accompany and denote the immediate influence of the paſſions of their minds. Beſides this more important uſe of the word, it is uſed in painting to ſignify the repreſentation of any object by a mode of execution agreeable to its nature, its character, and the ſituation it holds in the work. When wrought with juſt ſenſe and propriety in theſe reſpects, it is ſaid to be *well expreſſed*. We will firſt conſider it in the former and more uſeful ſenſe.

The paſſions which influence the conduct of men have each a general character of expreſſion, by look or geſture, attached to them in the whole race of mankind ; and they are alſo marked in individuals by peculiarities, ariſing from the temperament and conſtitutional habits with which each of them is endowed by nature.

To ſeize and repreſent with energy theſe characteriſtics of the paſſions of the mind, and accompany their repreſentation without diminiſhing its force, with the varieties appropriate to the individual perſonages introduced into a picture, is the eſſence, the ſoul of art. The ſlighteſt ſketch poſſeſſing this quality, acquires an intereſt uninſpired by, and far above, that excited by the moſt highly and excellently wrought pictures which are void of it.

Very few painters, amongſt the immenſe numbers of thoſe who lay claim to the name, have been happy enough to obtain a ſuper-eminent degree of expreſſion in their works; indeed it is a taſk of extreme difficulty to overcome, requiring the ſoundeſt ſenſe to ſelect the knowledge of it, and the greateſt ability in art to repreſent it when underſtood. The man who aims at it, beſides being an ever active obſerver, ſhould poſſeſs great ſuſceptibility of mind to enter into the feelings of others, and thus draw, as it were, from himſelf: yet that ſuſceptibility ſhould be under the regulation of ſound diſcernment, and cool diſpaſſionate judgment, to enable him to diſcriminate the fictitious repreſentations of paſſion, from thoſe natural unartificial actions, and looks, dictated by, and ariſing from, genuine feeling: and in his continued obſervations upon the actions and aſpects of men under their influence, he ſhould be careful to ſeparate thoſe points which identify a peculiar paſſion, and diſtinguiſh it from others that are nearly allied to it.

Artiſts endowed with very conſiderable talents have failed in two different ways in their endeavours to embelliſh their works with this valuable quality. Some, by an over-anxious deſire to give ſtrength and energy to their expreſſions, have carried them into artifice and bombaſt: others, on the contrary, wiſhing to unite the beautiful with the pathetic, have only rendered their works inſipid and unintereſting in expreſſion; and it appears that he who is obliged to labour to produce it, who does not work from a clear comprehenſion of the characteriſtic lines of an expreſſion in its ſimpleſt and moſt undiſguiſed ſhape, can never effect the repreſentation of it to any degree of perfection, and the beholder of his works will ſtill leave them unimpreſſed with any portion of the ſenſation the real paſſion is calculated to produce; the only true teſt of the value of works of art, as far as relates to expreſſion.

> " By tedious toil no paſſions are expreſt,
> He who conceives them ſtrongeſt paints them beſt."

The power of rendering, or producing expreſſion in painting, is, next to grace and elegance, the leaſt communicable talent of thoſe requiſite to form a perfect painter. He who attempts to obtain it, if not originally gifted by the great Author of nature with a peculiar propenſity to obſerve and imbibe the leading features which conſtitute its excellencies, follows a phantom that will for ever elude his graſp. If, however, he happily poſſeſſes that inclination, he may obtain ſome aſſiſtance in his purſuit of it from the works of others, which will ſhorten his labour, but will not lead him to the ultimate point of his deſire; to that, the ſtudy of nature can alone effectively induce.

We allude to ſome general rules given by artiſts who have communicated the reſult of obſervations made in their endeavours to obtain an underſtanding of the expreſſion of the paſſions of the mind, in the countenances and actions of men; and they are by ſome, whoſe names authorize reliance upon their obſervations, particularly Lionardo da Vinci, Trattata de la Pittura, and Le Brun's Paſſions. They have pointed out and illuſtrated thoſe actions of the countenance and figure which moſt ſtrongly deſignate the reigning influence of particular paſſions.

Theſe rules, however, go only a ſhort way in a general view of the ſubject; much leſs do they comprize what is requiſite, when the multitudinous varieties of expreſſion in the almoſt infinitely varying countenances and habits of men of all degrees are taken into conſideration. How, indeed, can it be poſſible to direct the means of obtaining with certainty that which is in itſelf ſo infinitely diviſible, as the courſe of the feelings and dictates of the ungovernable heart of man, and his correſponding actions and turns of feature?

It is in having aſcertained and eſtabliſhed the features of the more ſtrong and leading paſſions, that theſe general rules are found uſeful. We learn from them, that the influence of exceſſive joy or laughter draws all the features of the face upwards; that grief reverſes that order, and draws them downwards. Violent anger diſtorts them, and enlarges their appearance, particularly the eyes and noſtrils; and the action of the body is violent, with quick and ſhort motions. Deſire enforces an eager advancing action towards its object, and the eyes and mouth are ſomewhat expanded. Acute pain is generally expreſſed by a mouth ſomewhat opened and drawn back, the eyes raiſed, and partly covered by the upper eye-lid; and the eye-brows drawn cloſely together, wrinkling the forehead. Fear is denoted by expanded eyes and mouth, the eye fixed upon the exciting cauſe, the hair elevated and thickened, the colour livid, and the figure drawn back as if attempting to retire from the object which cauſes the alarm. The effects of the ſenſation of ſcorn or hatred on the figure and countenance are marked by the mouth being cloſed firmly, and the lips drawn down at the corners; whilſt the elevation of the noſtril cauſes the middle of the upper lip to riſe; the forehead is ſtrongly preſſed, and the brow falls over the eyes, which expreſs the paſſion beſt when they are turned ſideways, towards the object, with the body inverted from it. Awe, or veneration, produces a general inclination of the body, and the head ſtill more ſo, towards the object exciting it.

Under one or other of theſe paſſions and expreſſions all the feelings of our minds are more or leſs ranged; and of courſe will participate more or leſs of the indications of them, according to the excitation they meet with: therefore, ſo far the general rules will be of uſe in their repreſentation. But mankind, from their various modes of education, their habits, and manners, accompany theſe ſenſations, when excited in them, by peculiarities which it is of the utmoſt importance to the painter juſtly to diſcriminate, and be careful not to give that action to one, which, in propriety, belongs to another; not to attach the vulgar action of an uncultivated clown, to the dignified character of a man of rank and liberal education.

Beſides remarking the expreſſive characters of the ſtronger paſſions, great attention is requiſite to be paid to the phyſiognomical expreſſion of the countenance, and of the figure (if one may ſo ſpeak); the influence of which is daily felt and acknowledged. Though our information upon that ſubject is much thwarted by the effect of education and reflection, yet its baſis is juſt and firmly fixed, as every day's experience proves. Perſons whoſe features and general forms correſpond, are found to be correſpondent alſo in character; that is, in their natural propenſities: one of two, thus ſimilarly formed, may have cultivated his mind more than the other, and education and ſociety may have taught him to maſk or diſguiſe his inclinations; but nature is ſtill true to herſelf, and the ſame general diſpoſition remains. Nay, it goes ſtill further; young perſons not naturally addicted to vice, being drawn by accident or early aſſociation to continue in the practice of indulgence, acquire, in proceſs of time, a change of feature and expreſſion, in great meaſure ſimilar to that form uſually indicative of the vice or paſſion indulged in, where it is implanted by nature.

In this, therefore, we have a ground of expreſſion which is well worthy, indeed very neceſſary, to be carefully attended to by thoſe who aim at perfection in the art of painting. They ought to make themſelves acquainted with the forms that belong to the peculiar inclinations and different degrees of capacity of mind in the perſons they chuſe to bring forward in their works, of whatever claſs they may be. They ſhould not put into the face of a man of mild character any of the features indicative of warm paſſions; in ſuch an one the eye ſhould not have an eager look; the noſtrils ſhould not be large, or inflated; all the lines ſhould be ſmooth, and have little variation of form. And, on the contrary, when the figure of one whoſe diſpoſition is naturally hot and impetuous is introduced, he ſhould not have a ſmooth ſtraight forehead; which is indicative of mildneſs and ſuavity; his noſe ſhould not be ſtraight; nor his mouth gently undulating, of a mild pleaſing character: though he may not be in the act of exerting his natural impetuoſity of character, yet he ſhould have the appearance of one who would be eaſily rouſed to that feeling and expreſſion. A man of great ſenſe and intellect ſhould not be repreſented with the features that characterize imbecility; nor the weak, and undecided character, have the forms denoting ſenſe and intellectual power; and it ſhould be conſtantly remembered, that though every paſſion, every ſentiment of the mind, has its peculiar expreſſion; every particular perſon has his peculiar mode of expreſſing it.

In repreſentations of the paſſions, 'tis not form alone which is required to perfect the work: though that indeed yields a very ſtrong impreſſion of it, yet its effect is greatly heightened when a proper tone of colour is ſuperadded. By colour we judge of health or ſickneſs, of youth and age, as well as by form. The ſallow hue of melancholy is proverbial. It is well known how anger affects the hue of the countenance; in ſome it produces a violent fluſh of blood, and conſequent redneſs of colour, even almoſt to blackneſs: in others a pallid hue denotes it, or a change from one to the other rapidly ſucceeding. The malignant paſſions are generally accompanied in their expreſſions by a pallid tone of colour: and the more noble ſentiments by the reverſe. A man performing a benevolent action feels a degree of ſatisfaction which affects his countenance; his eyes exhibit his ſentiments by their livelineſs, and his mouth by its gentle curves at the corners, whilſt his cheeks bear (what is perfectly underſtood ſo as to be admitted a common phraſe) the cheerful glow of humanity ſtampt on them. Clearneſs of complexion, and colour in the cheeks, indicate youth and health; ſallowneſs, and the loſs of the ruddy hue of colour, ſickneſs and age. The inhabitants of the town, and of the country, exhibit the ſame diſtinctions; as alſo the ſtudious man and the ſportſman. Independent of the individual hue of the character repreſented, one general tone over the whole picture ſhould prevail, correſpondent to the ſubject. Thus, if it be one of a grave caſt, the tone of colours ſhould be low, yet rich; and though harmonious not monotonous. If, on the contrary, the ſubject is gay, the hues of the colouring ſhould be bright and cheerful, and greatly diverſified; and every part of the picture ſhould aſſiſt in expreſſing the nature of the ſubject choſen for repreſentation.

It is attention to this point which gives to painting its real value, its intrinſic worth; and ſeparates it from the

mere

more vulgar or merely mechanical arts. Hence it becomes of moral utility, and its power is not ſurpaſſed by the poetic, or other effuſions of the pen, in the force and vivacity of the impreſſions it is calculated to produce. Of this there are many notices given to us in hiſtory. Alexander is ſaid to have trembled and grown pale on ſeeing a picture of Palamedes betrayed to death by his friends: it bringing to mind the remembrance of his treachery to Ariſtonicus. It is alſo related of an Athenian courtezan, that in the midſt of a riotous banquet, caſting her eye on the portrait of a philoſopher marked with the happy character of virtue and temperance; ſhe was ſtruck with ſo lively an image of her own unworthineſs, that ſhe inſtantly went home and became an example of temperance. In both theſe caſes, to the truth of the expreſſion muſt be aſcribed the force with which the pictures wrought upon the obſervers; and produced the powerful impulſe related.

It appears, indeed, to have been the principal object of attention with the ancient Greeks, and very naturally ſo; for in the beginning of an art, before any rules for regulating its efforts were adopted the artiſt's attention muſt of courſe have been ſolely directed to relating his ſtory; and whatever aſſiſted in effecting that, was preſſed into the ſervice. Firſt of all, we are told, the efforts were ſo rude it was neceſſary to explain them: afterwards labels were placed as iſſuing from the mouths of figures; and other means of giving the ideas, ſuppoſed to occupy their minds, were adopted, till at laſt the artiſts arrived at the perfection of imitations of nature; and by giving their figures the actions and expreſſions appropriate to their ſituations, cauſed them to tell their own ſtory, and impreſs all its intereſt on the beholders, without any extraneous aid. Unhappily, excepting the few pictures found at Herculaneum, and thoſe are of a trivial kind, we have none of their works in this art to judge of the degree of perfection they arrived at in this moſt important point of it; but we have the teſtimony of many authors, ſome of whom ſpeak as eye-witneſſes, by whom we are led to believe, on convincing grounds, that their beſt pictures were full fraught with this beſt of good qualities; and there is no reaſon to doubt the truth of the report, when we ſee the ſculpture of the ſame period which remains to us, ſo rich in poſſeſſion of it.

In their ſtatues, which were principally of gods, a great degree of minutiæ of expreſſion does not appear to have been the object of their attention, as far as relates to the paſſions, the repreſentation of which they ſeem properly to have regarded as degrading to the dignity of a divinity. A calm unruffled ſtate of mind appears in their countenances, and governs their looks and actions, but each has its appropriate character. What can be more dignified and majeſtic than the countenance of the Jupiter? Yet the line which its air, partaking ſomewhat of ſeverity, inſpires, is ſo blended with mildneſs, that it produces implicit confidence and veneration. The Apollo Belvedere has alſo the dignity of the godhead ſhining in it; but leſs impoſing and overpowering, of a milder character, and the expreſſion of his figure and action is perfect; no one doubts the intent of it for an inſtant; and this juſt diſcernment, and impreſs of character, run through the whole claſs of ſtatues of the primary deities of the Greeks. The Venus, the Bacchus, the Hercules, &c. have each their diſtinctive line of character without paſſion, whoſe influence they are ſuppoſed to be exalted above, whilſt in the lower orders, the fauns and nymphs, and rural deities, are no leſs properly marked with characteriſtic features and actions. In the figure of Laocoon deſtroyed with his ſons by ſerpents, the authors (who were three) have exhibited a moſt powerful extent of feeling and power in expreſſion, remaining almoſt unrivalled in ſubſequent productions; the agony of pain and diſtreſs of mind are ſpread over the whole work which chills the beholder with horror.

Correſpondent with this powerful effect is that related of and attributed to their pictures. Pliny ſays of Ariſtides, "that he infuſed into his pictures all the paſſions of the ſoul." It is ſaid, "that Parrhaſius, in his picture of Philoctetes, had renewed the pains of the hero, as ſeen in his parched deep ſunk eyes, and the tears which flowed from them;" (Anthol. lib. 4.) and the epigrammatiſt concludes with a handſome compliment to the painter, blaming him "for not allowing the ſufferings of Philoctetes to end with his life." Philoſtratus, Vita Apollonii. cap. 10. ſays, ſpeaking of the Ajax of Timotheus, "we cannot do juſtice to the picture where Ajax is repreſented diſtracted, unleſs we previouſly form in our minds the image of his condition. The picture of "Medea contemplating the Murder of her Children," by the ſame painter, was the ſubject of numerous epigrams (Anthologia); ſo that it muſt have been very powerful to excite ſo much emulation among the wits to celebrate it. It was ſaid to repreſent in her face, fury mixed with pity of the innocence of her children, who were repreſented ſmiling at the dagger in her hand. Ovid ſays, "her crime was confeſſed in her eyes." Plutarch ſays of Lyſippus the painter, that he was ingenious as well as ſublime; that from the ſlight inclination of the neck natural to Alexander, he invented a ſublime expreſſion; making him look up to the heavens with manly boldneſs, and commanding majeſty. The ſame author (in Timoleon) praiſes the paintings of Nicomachus "for their juſt expreſſion," comparing them "to the poetry of Homer in grace and facility:" and Apelles in this point affirmed himſelf ſuperior to other painters, though inferior in ſome others of leſs importance. It is needleſs to repeat the well known ſtory of Timanthe's picture of the Sacrifice of Iphigenia, and of his artifice in hiding the face of the father, having exhauſted the force of expreſſion in the beholders; commendations and imitations of it are met with every where; and of his ingenious contrivance to convey an idea of the immenſe ſize of a Cyclops, by drawing ſome Satyrs meaſuring his figure with a thyrſus; and Pliny remarks of him on this occaſion, that "in all his works there is more underſtood than is marked, and though his execution be maſterly, yet his ideas exceed it."

Whatever allowance be made for the zeal and ſtrength of terms with which perſons at all times deſcribe thoſe things, than which they are unacquainted with any thing better, and which muſt have been the caſe in the early periods of art, the writers not being ſo learned in it as the painters who made it their continual ſtudy; yet we cannot refuſe belief to a wonderful extent of power in rendering expreſſion among the Greek painters, accompanied, as (it has been before obſerved) theſe deſcriptions of it are, by the actual effect in ſculpture. It is more aſtoniſhing that it ſhould ever have been loſt ſight of; yet that was the caſe, and on the revival of the art of painting the old original futile means of labels, &c. were had recourſe to, till the gradual advance of learning and propriety of ſentiment again reſtored it in the 15th century to the juſt imitation of the impreſſions of nature. Maſſaccio was among the firſt who thus advanced it, but it was Lionardo da Vinci who firſt perfected its claim to intereſt over the mind, though, perhaps, in none of his works ſo completely as in his repreſentation of the Laſt Supper, painted on the walls of the refectory of the Dominican convent at Milan, where it ſhone for a period, unrivalled in truth and vigour of expreſſion.

It repreſents the moment wherein our Saviour has juſt ſaid to his diſciples "One of you ſhall betray me." Each figure has intelligence beaming from it; each individual exhibits a full report of what paſſes within his boſom. How tranquilly, yet how fully does our Lord diſcloſe this forerunner of his approaching miſeries, that one of thoſe whom he had loved and cheriſhed ſhould become treacherous, and turn his bounty to his ruin; and with what propriety is he thus repreſented tranquil, yet dignified! ſo conſiſtent with his high character and office! With what eagerneſs does the impetuous Peter apply to the well deſignated meek and humble John, to learn the name of the culprit that would betray ſo good a maſter! while that conſcious culprit, hearing the requeſt, ſtarts backward with alarm, fearing the conſequences of ſuch a diſcloſure. Theſe are repreſentations ſo powerful, that it needs but the regard of a moment to comprehend all ſaid, and to be ſaid, to complete the whole intereſt of the ſtory. The timid heſitating Thomas, at a ſmall diſtance from Peter, preſſes his hand on the other's ſhoulder, to urge him to make the requeſt his own timidity prevents him from doing himſelf. The next of the apoſtles, whoſe peculiarities hiſtory hath not ſo fully recorded, are repreſented in great variety of actions and expreſſions correſponding with, and juſtly originating in, the incredible circumſtance juſt announced to them. One, with his hands preſſed on his boſom, riſing, aſſerts his innocence; another ſtarts with ſurpriſe, and, in the pious conſciouſneſs of ſinful weakneſs, ſeems to demand "Lord, is it I?" One calmly, yet earneſtly, liſtens to the reſult of the queſtion urged by Peter: others, in contraſt with him, ſeem to argue together if it be poſſible ſuch iniquity could dwell with man, and in ſo doing declare their own innocence. Anxiety is depicted as diſturbing every breaſt, yet the peculiarities of each are preſerved with the moſt juſt diſcrimination; and all appear ſo impreſſed with nature, that while it is recognized as the offspring of that great man's genius, the mere imagination of his mind, it has the appearance of a portrait of the actual ſcene. It is now unfortunately much injured by time and cleaning, being painted in oil, and not, therefore, adhering to the wall ſo perfectly as freſco.

To become able to produce a work of this ſurpriſing power in expreſſion, Lionardo ſays of himſelf, that he loſt no opportunity which the occaſions of life afforded him, of ſtoring up remarks upon the nature of its action in men. He paid much attention to anatomy, and is ſaid to have attended executions, not only to watch the looks and actions of the ſufferers, but alſo to obſerve how the different perſons compoſing the crouds of ſpectators were affected. The common occurrences of life are every day affording the attentive and ingenious artiſt leſſons on this head; and he will ſucceed, accordingly as he is intelligent and active in obſervation of them; or if he neglects to improve his mind by them, is inattentive and unfeeling to them, he can never become equal to the taſk of repreſenting them.

Michael Angelo was alſo a powerful promoter of this high quality in works of art, but his expreſſion is of a grand and more myſtic nature than Lionardo's, and it is Raffaelle alone that has approached in his own way the ſuperior excellencies of the work we have above deſcribed. "We ſtand in awe of Michael Angelo," ſays M. Fuſeli, "while we embrace Raffaelle, and follow him wherever he leads us." He has not ſucceeded well where he has attempted the ſublime. His gods are not even heroes, and his heroes are common vulgar men, except in a few inſtances; but where tenderneſs, and the amiable qualities of human nature have been his ſubject, he is not behind his great forerunner. Nor in the relation of his ſtory is he ever deficient; ſometimes, indeed, as has been obſerved on the Cartoon of Ananias ſtruck dead, under the word ENERGY, in *Painting*, he combines the paſt events on which it depends, and the future, to which it leads. His Cartoons of "St. Paul preaching at Athens;" the "Healing the Lame Man at Lyſtra;" "Elymas ſtruck blind," are inſtinct with feeling and expreſſion: they are but ſlightly finiſhed, and lack the extreme perfection of Lionardo's work; however, from the high degree of character to which Raffaelle has carried ſome of his heads, in his picture of the "Transfiguration," 'tis fair to ſuppoſe he could have perfected theſe, if the nature of the works (being only examples for tapeſtry) had required it. In comparing the reputation of Raffaelle to Lionardo da Vinci in this reſpect, it ſhould not be forgot that he was only 36 years old when he died, and the latter was 49 or 50 when he painted the aſtoniſhing work of the "Laſt Supper." Had Raffaelle lived to an advanced age, it is probable he would have ſurpaſſed even him. The ſimplicity and fullneſs with which he deſcribes, or effects, the relation of his ſubject, is beautifully inſtanced in the Cartoons of "St. Paul and Barnabas healing the lame Man at Lyſtra," and the conſequent adoration paid to them. The apoſtles are raiſed upon ſome ſteps above the croud, and thus diſtinguiſhed, as well as by the attention of all being directed to them. The reſtored cripple is known from the reſt, by his eager demonſtrations of gratitude and adoration; by his united and uplifted hands and animated looks, addreſſed to his reſtorers, and by the crutches now become uſeleſs, and fallen at his feet to the ground. An aged man bending forwards, lifts with one hand the garments of the healed man, to view the limb now become perfect, and ſimply by the uplifting of the other, expreſſes his admiration of the cure ſo miraculouſly effected. It is the ſimplicity of the means Raffaelle uſes, which gives ſo much the appearance of nature to his expreſſions: no one, on ſeeing the works, doubts but that he ſhould have employed the ſame means; the art is loſt ſight of. The effect of the pictures of Raffaelle, in point of expreſſion, on the artiſt who obſerves them, is much the ſame as Garrick's acting the character of a clown is ſaid to have had upon a countryman, who completely loſt ſight of the actor, and criticiſed only the ſentiments, in which, by the by, he complimented the author alſo, by ſtating that he ſhould have done the ſame himſelf. Yet it is a fact, that no point in art is ſo difficult to attain as this true ſimplicity of character with effect. Perhaps the moſt beautiful piece of expreſſion in painting known to the world, is Raffaelle's head of the Madonna della Sedia, now in Paris. The ſweetneſs of ſentiment conveyed by the mouth is completely undeſcribable: no picture has been ſo frequently copied, none ſo rarely imitated.

Titian has frequently ſucceeded in rendering expreſſion in his works, though it is not his general characteriſtic. His picture of St. Peter Martyr, before alluded to, (ſee EXECUTION, in *Painting*,) is almoſt perfect in this, as well as in moſt other points. Indeed, when taken in the whole, we cannot help conſidering this as the moſt perfect picture in the world; poſſeſſing more of every good quality than any other we are acquainted with. It has ſtrongly the character of expreſſion, both in form, and correſpondent tone of colour. No man of feeling regards it, but with an inſtantaneous ſentiment of ſeriouſneſs; ſomewhat, indeed, of horror is inſpired by the firſt view of it; particularly by the figure of the monk who is running away, and who eyes the proffered palm of martyrdom itſelf with horror. In direct oppoſition to him is the figure of the ſaint; who, ſuffering under the power of the aſſaſſin, (in whoſe perſon nought but the ſentiment of brutality prevails,) turns his eyes towards the angels deſcending with the palm and crown, and hails the viſion of future glory. The hue of the picture, we have ſaid, is ſerious, and it is alſo rich and deep in colour; 'tis the effect of that hue which prevails at twilight, and is moſt judiciouſly choſen as ſuitable to the affecting nature of the ſubject. Raffaelle has employed it in his portrait of Leo X. with the cardinals Roſſi and Medici attending him. Here the ſubject was grand, and its effect is increaſed by the deep and ſerious tone of the colouring.

Pouſſin has, in ſeveral inſtances, been very happy in the expreſſion of his ſubject. One of his pictures we will mention as a very excellent model of it; 'tis the Judgment of Solomon, a picture bad in its colour, in its compoſition, and execution, but fraught with the quality we are now conſidering. The king is ſeated upon his throne, ſurrounded by his attendants, and has juſt given the command to divide the living child. A ſoldier is proceeding to execute the order, and this gives occaſion to the admirable diſplay of diverſity of feeling in the by-ſtanders. An old man ſeems coolly to reaſon with himſelf if the king can intend the performance of ſo cruel a ſentence. Another looks earneſtly forward with the vacuity of aſpect ſo commonly produced by ſurpriſe. A woman turns away her head to avoid the ſight, and her child clings to her ſide alarmed. A ſoldier regards the ſcene with a countenance fraught with pity, another turns from it with diſguſt. Whilſt the wicked, abandoned woman, who had ſlain her own child, ſeeks the deſtruction of her neighbour's alſo; the real mother implores, with an earneſtneſs never to be too much admired, the preſervation of her child; rather willing to diſown, than to ſee it deſtroyed. The expreſſion of the action of the king is completely that of conviction to whom the child belongs; he almoſt ſeems to exclaim, now I ſee the right, now I know to whom to give the award. Pouſſin has alſo in this inſtance added another uſeful indication of character in the attire of the woman, no leſs different in mind, than in habit. He has given to the vicious creature that negligence in dreſs which is too often indicative of a general habit of idleneſs and neglect; whilſt he has dreſſed the other with decent care, and propriety.

This great painter has in another picture exhibited the force of colour in rendering expreſſion, almoſt independent of form: 'tis in his picture of the deluge; one of a ſeries of four pictures meant to repreſent the four ſeaſons of the year. It is almoſt entirely of one hue. The compoſition conſiſts of little more than a large portion of ſky and water; the latter in the lower part of the picture falling in a cataract. In the diſtance is the ark, ſcarcely diſcernible through the thickneſs or dullneſs of vapour, through which the ſun is with difficulty alſo ſeen, of a reddiſh hue. In the loweſt corner of the picture is a family, conſiſting of a man, his wife, and child, endeavouring to climb from a boat upon a rock, on which a ſerpent glides along; and a little farther towards the centre are ſeen the heads of a man and horſe juſt ſinking in the water. With theſe ſlight materials has Pouſſin wrought a picture which is completely overpowering in its melancholy effect. It is ſaid that Rouſſeau would ſit enwrapt in ſilence over it for hours, gratified with the ſenſations it inſpired.

Another maſter, whoſe attempts to render expreſſions have been ſometimes very ſucceſsful, is Guido Rheni; but he ſeldom goes farther than the characters of ſaints in pious ejaculations, Magdalens in the moment of contrition, and Ecce Homos. Of the latter, there is one of ſuper-excellent perfection, in the poſſeſſion of B. Weſt, eſq. a head only, but full of feeling; ſurely "never was ſorrow like unto his ſorrow," may be as juſtly applied to the painting, as to the ſufferings of the divine original. There is an ancient painting of a Satyr's head, now in the Barberini palace at Rome, which is eminently diſtinguiſhed by expreſſion of character.

There are but few among the large maſs of the Italian and French painters who have ſucceeded in their efforts (to any pre-eminent degree) in giving expreſſion to their works in its more exalted ſenſe. Ludovico Carrache, and Domenichino have ſometimes effected it, but rarely, and Annibal Carrache ſtill leſs frequently, notwithſtanding his immenſe power in execution. Among the Flemings, Jan Stein, and Oſtade, hold the principal places. The former particularly is exceedingly happy in characterizing the aſpects and manners of that claſs of men he undertook to paint, and he does it with great freedom and eaſe. Oſtade is more laboured in his manner, but perfect in his finiſh in the confined ſcale in which he exerted himſelf. Rubens has ſometimes ſucceeded to a high degree in this quality, but, in general, the expreſſions of his figures in ſerious ſubjects are too violent, and outſtep the modeſty of nature. In the gayer ſcenes, where nymphs and fawns are fancifully indulging their humours, his power is complete; they live and breathe with all their native gaiety and animation; and in expreſſing the characters of beaſts, either calm or enraged, not even Snyder has ſurpaſſed him. Vandyke rarely appears to have felt it in his hiſtorical pictures; but in ſome of his portraits he is extremely happy. His Cardinal Bentivoglio is a perfect inſtance of expreſſion in this branch of art. His picture of lord Strafford and his ſecretary at Wentworth-houſe, Yorkſhire, is another; but the idea is taken from Titian; whoſe portraits are maſter-pieces of identical character and expreſſion, and the prototype of Vandyke's excellence. In this reſpect, ſir Joſhua Reynolds is no leſs happy than either of them: prints from whoſe pictures are in ſo many hands, and ſo generally known, that it is needleſs to exemplify the aſſertion by further remark, yet we cannot decline mentioning the picture of Mrs. Siddons in the character of the Tragic Muſe, as a very happy inſtance of his power.

Rembrandt, though ſeldom happy in repreſenting the purity of expreſſion in his figures, yet ſometimes effects it; but his great characteriſtic is the truth with which he gives expreſſion in the ſecondary ſenſe we have affixed to it, as regarding painting. To imitate the peculiarities of nature was his delight. He ſeized and expreſſed, with the greateſt truth, the moſt extraordinary effects of the illumination of objects, and gave it its greateſt poſſible brilliancy and force. In a different line, Netſcher and Metzu were highly ſkilful in the exact expreſſion of the nature of the objects they choſe to repreſent. Silks, furs, carpets, metals, &c. all are expreſſed by them with the greateſt truth, and in a free, broad ſtyle of execution, particularly by the former. Teniers, and in ſhort almoſt all the painters of the Dutch and Flemiſh ſchools, have exhibited great ability in expreſſing the character of natural objects. But to this ſtudy they ſacrificed attention to expreſſion in its more elevated and uſeful province.

Not ſo our inimitable Hogarth. Though he took the common ſcenes of nature as his field of action; and was not unſkilful in imitating the natural effect of objects; yet with him this meaner talent was of ſecondary conſideration. By his pencil he inculcates leſſons of morality, and no lectures from the pulpit are more effectually ſtrong and convincing, than thoſe conveyed by his pictures. Witneſs the Rake's, and the Harlot's Progreſs; where the evils attendant on vice, and the bleſſings which a courſe of virtue is calculated to produce, are ſo powerfully exemplified. With what force has he ſatirized pride and luxury in his Marriage-a-la-Mode; bigotry, ſuperſtition, and folly, in many of his other works!

and no one has ever expreſſed identical character more ſtrongly than he has. The figure of the exhauſted rake in the breakfaſt-ſcene of the Marriage a-la-Mode, has never been ſurpaſſed in truth and force. We could enlarge with pleaſure upon his value in this point of view, but content ourſelves with recommending his works with the excellent comments upon them by Mr. J. Ireland, to the peruſal and obſervation of our readers; and are proud to have ſo excellent an exemplar of the value of expreſſion in painting as Hogarth, whoſe talents were native, unindebted to foreign ſchools, in praiſe of whom to conclude our obſervations on this very important point.

EXPROBATION, Exprobatio, in *Rhetoric*, is the reproaching a perſon with ingratitude, and unmindfulneſs of ſome particular benefit conferred upon him.

EXPUGNATION, in *Military Language*, the taking of any place by aſſault.

EXPULSION, the act of driving a man by force out of a city, community, or the like.

Expulsion is alſo uſed for the act of driving out a foreign body with violence from the place it was in.

The uterus has the chief office in the expulſion of the fœtus; if the expulſion of the fœtus happen very ſoon after conception, it is called a *falſe birth*. See Delivery, Foetus, and Labour.

EXPURGATION, in *Aſtronomy*, is uſed by ſome authors for that ſtate or action of the ſun, wherein, after having been eclipſed and hid by the interpoſition of the moon, it begins to appear again.

Later aſtronomers call this emerſion, not expurgation.

EXQUIMA, in *Zoology*, the name of a ſpecies of monkey common on the coaſt of Guinea, of which Ray enumerates two or three varieties. See Simia.

EXSIBIDANTES, in *Antiquity*, a kind of hiſſers, who, in the theatre, and other public auditories, uſed to make a noiſe with their feet, and even ſometimes beat the ſeats with battons.

EXSICCATION, formed of *ex* and *ſiccus*, *dry*, in *Chemiſtry*, *Pharmacy*, &c. the act of drying up or evaporating the moiſture of a thing. For this purpoſe two methods are uſually employed: in one of which the humidity is evaporated by heat, and in the other it is imbibed or abſorbed by ſubſtances adapted to the purpoſe. Bodies combined with, or diſſolved in a fluid, require the firſt mode, and to ſuch as are only ſuperficially blended with it, the ſecond mode is applicable. Vegetables are commonly exſiccated by the natural warmth of the air, though the aſſiſtance of artificial heat is often very uſeful. By a moderate fire the more tender flowers may be ſoon dried without any conſiderable loſs, either of their odour or lively colour, which would be injured, if not deſtroyed, by a more ſlow exſiccation in the air. Some plants, particularly thoſe of the more acrid kind, loſe their virtues by this proceſs.

EXSORS Particula. See Particula.

EXSUCCATIO, a word uſed by ſome *Chirurgical Writers*, to expreſs an enchymoſis, or ſuggillation.

EXSUFFLATION, a ceremony obſerved in baptiſm, by which the candidate was ſuppoſed to renounce the devil. See Baptism.

EXTACY, Εξϛασις, a rapture, or removal of the mind out of its natural ſtate and ſituation; or a tranſport, whereby a perſon is hurried out of himſelf, and the office of his ſenſes is ſuſpended. See Enthusiasm.

Extacy, in *Medicine*. See Ecstasis.

EXTANT, ſomething that ſtill ſubſiſts, or is in being.

It is but part of the hiſtory of Livy, of the writings of Cicero, Cæſar, &c. that are extant, the reſt are loſt. We have nothing extant of Socrates, though he wrote a great deal.

EXTEMPORANEOUS Prescription. See Prescription.

Extemporaneous *Playing*, flights in *Muſic*, on a harpſichord, or piano forte, have many appellations; as toccata, toccatina, *Ital.* prelude, capriccio. On the organ it is called a voluntary.

There have been organiſts, whoſe abilities in unſtudied effuſions on their inſtruments have almoſt amounted to inſpiration, ſuch as Sebaſtian Bach, Handel, Marchand, Couperin, Kelway, Stanley, Worgan, and Keeble, ſeveral of whom played better muſic extempore, than they could write with meditation.

EXTEND, in the *Manege*. To extend a horſe, is an expreſſion uſed by ſome to import the ſame with making a horſe go large. See Large.

Extend, in *Military Language*. When the files of a line, or the diviſions of a column, are to occupy a greater ſpace of ground, they are ſaid to extend their front or line.

Extend, in *Law*. See Extending.

EXTENDENDA Terra. See Terra.

EXTENDI Facias, in *Law*, a writ of extent, whereby the value of lands is commanded to be made and levied, &c. Reg. Orig. See Extent.

EXTENDING, in a *Legal Senſe*, ſignifies the valuing of lands and tenements of one bound by ſtatute, &c. and who hath forfeited his bond at ſuch an indifferent rate, as that by the yearly rent the obligator may in time be fully paid his debt. See Extent.

EXTENSION, in *Philoſophy*, is one of the general and eſſential properties of matter; the extenſion of a body being the quantity of ſpace which the body occupies, the extremities of which limit, or circumſcribe, the matter of that body. It is otherwiſe called the *magnitude*, or *ſize*, or *bulk* of a body.

A quantity of matter may be very ſmall, or ſo as to elude the perception of our ſenſes, ſuch as a particle of air, a particle of water, &c.; yet ſome extenſion it muſt have, and it is by the compariſon of this extenſion, that one body is ſaid to be larger than, equal to, or ſmaller than, another body. The meaſurement of a body conſiſts in the compariſon of the extenſion of that body with ſome determinate extenſion, which is aſſumed as a ſtandard, ſuch as an inch, a foot, a yard, a mile; hence it is ſaid, that a body is a foot long, or three inches long, &c.

The extenſion of a body is meaſured three different ways; or a body is ſaid to have length, breadth, and thickneſs. Thus an ordinary ſheet of writing paper is about 16 inches long, about 14 inches broad, and nearly one hundredth part of an inch thick. Either of theſe dimenſions might be called the length, or the breadth, or the thickneſs; but, by general cuſtom, the greateſt extenſion is called the length, the next is called the breadth, and the ſhorteſt is called the thickneſs. The outſide of a body, its boundary, or that which lies contiguous to other bodies that are next to it, is called the *ſurface* of that body, and this ſurface has two dimenſions only, *viz.* length and breadth; but it has no thickneſs, for if it had, it would not be the outſide of the body; yet a ſurface by itſelf cannot exiſt. In mathematics, however, ſurfaces are mentioned, and are reaſoned upon, abſtractly from matter. But in theſe caſes the ſurfaces exiſt in the imagination only, and even then our ideas have a reference to body, for our ſenſes cannot perceive a ſurface without a body.

As a ſurface is the outſide or boundary of a body, ſo a *line* is the boundary of a finite ſurface. Suppoſe, for inſtance, that a ſurface is divided into two parts, the common boundary of the two parts is called a line; and this has one extenſion only, *viz.* it has length.

The beginning, or the end of a line, or the interſection of two lines which croſs each other, is called a *point*, and this has no dimenſions; or, according to the mathematical definition, a point is that which has no parts or magnitude. Thus, if you divide a line into two parts, the diviſion or boundary between the two parts is a point.

Our ſenſes are only capable of perceiving bodies which have three dimenſions; or rather the ſurfaces of bodies, which ſurfaces have two dimenſions, but a ſurface cannot be repreſented nor perceived without a body, and of courſe neither a line nor a point can be perceived without a body. In the ſtudy of geometry, and in a variety of other branches, ſurfaces, lines, and points are repreſented upon paper, or upon ſomething elſe; but in thoſe caſes, the paper or that ſomething elſe is the body whoſe ſurface we perceive, and the ſurface of a particular figure is circumſcribed, not by real lines, but by a narrow ſlip of ſurface, which is ſufficient to direct our reaſoning with reſpect to the geometrical properties of lines and ſurfaces. Thus alſo when points are repreſented by themſelves, the marks are not real points, but very ſmall portions of the ſurface of a body.

There is a caſe in which extenſion is often ſaid to be perceived without the exiſtence of a body, and this is the extenſion between two bodies. But, upon conſideration, it will eaſily be comprehended, that we may perceive the two bodies, and that they are ſeparate from each other; but we cannot perceive any thing poſitive between them. So that in this caſe the word extenſion is uſed in a figurative manner, as if ſome other body exiſted between the two bodies.

The particular extenſion, whether under the name of inch, foot, yard, metre, league, &c. with which other extenſions are compared, or by which they are meaſured, are eſtabliſhed only by the common conſent or agreement of perſons of a certain nation, or profeſſion, and are uſed as ſtandard meaſures by them only. Hence, the meaſures of different nations, though ſometimes they have the ſame name, do, however, differ conſiderably from each other. Great endeavours have been made by divers ingenious perſons, at different times, for the purpoſe of determining an unalterable univerſal ſtandard of meaſures; but thoſe endeavours, and the ſucceſſes with which they have been attended, will be found deſcribed under the article STANDARD *of Meaſures*.

Extenſion is uſually deſcribed as conſiſting in the ſituation of parts beyond parts, with which ſome authors cavil, maintaining, that we can conceive abſolute extenſion without any relation to parts.

If a man conſider the diſtance between two bodies abſtractedly, and without any regard to bodies which may fill that interval, it is called ſpace; and when he conſiders the diſtance between the extremes of a ſolid body, it is called extenſion.

Extenſion is frequently confounded with quantity and magnitude; and, for what we can perceive, without much harm, the thing ſignified by them all appearing to be the ſame; unleſs we admit a diſtinction made by ſome authors, that the extenſion of a body is ſomething more abſolute, and its quantity and magnitude more reſpective, or implying a nearer relation to much and little. See QUANTITY, MAGNITUDE, MASS, and MATTER.

The infinite diviſibility of extenſion has been a famous queſtion in all ages. It is not eaſy to reconcile the doctrine of mathematicians on this head with the tenets of ſome philoſophers. They who hold that all extenſion and magnitude are compounded of certain *minima ſenſibilia*; and that a line, for inſtance, cannot increaſe or decreaſe, but by certain indiviſible increments or decrements only, muſt, conſiſtently with themſelves, affirm, that all lines are commenſurable to each other, contrary to the tenth book of Euclid, who demonſtrates that the diagonal of a ſquare is incommenſurable to its ſide. But if all lines were compoſed of certain indiviſible elements, it is plain one of thoſe elements muſt be the common meaſure of the diagonal and the ſide. This is a gordian knot which none of the philoſophers have yet thought fit to untie.

Biſhop Berkeley obſerves, that the infinite diviſibility of finite extenſion, though it is not expreſsly laid down either as an axiom or theorem in the elements of geometry, yet is throughout the ſame every where ſuppoſed, and thought to have ſo inſeparable and eſſential a connection with the principles and demonſtrations in geometry, that mathematicians never admit it into doubt, or make the leaſt queſtion of it. (See DIVISIBILITY.) And as this notion is the ſource from whence do ſpring all thoſe amuſing geometrical paradoxes, which have ſuch a direct repugnancy to the plain common ſenſe of mankind, and are admitted with ſo much reluctance into a mind not yet debauched by learning; ſo is it the principal occaſion of all that nice and extreme ſubtility which renders the ſtudy of mathematics ſo difficult and tedious. Hence, ſays he, if we can make it appear, that no finite extenſion contains innumerable parts, or is infinitely diviſible, it follows, that we ſhall at once clear the ſcience of geometry from a great number of difficulties and contradictions which have ever been eſteemed a reproach to human reaſon, and withal make the attainment thereof a buſineſs of much leſs time and pains than it hitherto hath been.

Every particular finite extenſion, which may poſſibly be the object of our thought, is an idea exiſting only in the mind, and conſequently each part thereof muſt be perceived. If therefore, ſays this author, I cannot perceive innumerable parts in any infinite extenſion that I conſider, it is certain they are not contained in it; but it is evident, that I cannot diſtinguiſh innumerable parts in any particular line, ſurface or ſolid, which I either perceive by ſenſe, or figure to myſelf in my mind; wherefore, I conclude they are not contained in it. Nothing can be plainer to me than that the extenſions I have in view are no other than my own ideas; and it is no leſs plain, that I cannot reſolve any one of my ideas into an infinite number of other ideas; that is, that they are not infinitely diviſible. If by an infinite extenſion be meant ſomething diſtinct from a finite idea, I declare I do not know what that is, and ſo cannot affirm or deny any thing of it. But if the terms extenſion, parts, and the like, are taken in any ſenſe conceivable; that is, for ideas; then to ſay a finite quantity or extenſion conſiſts of parts infinite in number, is ſo manifeſt a contradiction, that every one at firſt ſight acknowledges it to be ſo. New Theory of Viſion, § 54, 55. Analyſt. § 31.

On the other hand, it is obſerved by an eminent mathematician, that geometricians are under no neceſſity of ſuppoſing that a finite quantity or extenſion conſiſts of parts infinite in number, or that there are any more parts in a given magnitude than they can conceive or expreſs: it is ſufficient that it may be conceived to be divided into a number of parts equal to any given or propoſed number; and this is all that is ſuppoſed in ſtrict geometry concerning the diviſibility of magnitude. It is true, that the number of parts into which a given magnitude may be conceived to be divided, is not to be fixed or limited, becauſe no given number is ſo great but a greater than it may be conceived and aſſigned: but there is not therefore any neceſſity for ſuppoſing that number infinite; and if ſome may have drawn very abſtruſe conſequences from ſuch ſuppoſitions, they are not to be imputed to geometry. Geometricians are under no neceſſity of ſuppoſing a given magnitude to be divided into an infinite number of parts, or to be made up of infiniteſimals; nevertheleſs, they cannot ſo well avoid ſuppoſing it to be divided into a greater number of parts than may be diſtinguiſhed in it by ſenſe in any particular determinate circumſtance. But they find no difficulty in conceiving this; and ſuch a ſuppoſition does not appear to be repugnant to the common ſenſe of mankind, but on the contrary to be moſt agreeable to it, and to be illuſtrated by common obſervation. It would ſeem very unaccountable not to allow them to conceive a given line, of an inch in length for example, viewed at the diſtance of 10 feet, to be divided into more parts than are diſcerned in it at that diſtance; ſince by bringing it nearer, a greater number of parts is actually perceived in it. Nor is it eaſy to limit the number of parts that may be perceived in it when it is brought near to the eye, and is ſeen through a little hole in a thin plate? or, when by any other contrivance it is rendered diſtinct at ſmall diſtances from the eye. If we conceive a given line that is the object of ſight to be divided into more parts than we perceive in it, it would ſeem that no good reaſon can be aſſigned why we may not conceive tangible magnitude to be divided into more parts than are perceived in it by the touch; or a line of any kind to be divided into any given number of parts, whether ſo many parts be actually diſtinguiſhed by ſenſe, or not. In applying the reaſonings and demonſtrations of geometricians on this ſubject, it ought to be remembered, that a ſurface is not conſidered by them as a body of the leaſt ſenſible magnitude, but as the termination or boundary of a body; a line is not conſidered as a ſurface of the leaſt ſenſible breadth, but as the termination or limit of a ſurface; nor is a point conſidered as the leaſt ſenſible line, or a moment as the leaſt perceptible time; but a point as a termination of a line, and a moment as a termination of a limit of time. In this ſenſe they conceive clearly what a ſurface, line, point, and a moment of time is; and the poſtulata of Euclid being allowed and applied in this ſenſe, the proofs by which it is ſhewn, that a given magnitude may be conceived to be divided into any given number of parts, appear ſatisfactory; and if we avoid ſuppoſing the parts of a given magnitude to be infinitely ſmall, or to be infinite in number, this ſeems to be all that the moſt ſcrupulous can require. See Maclaurin's Treatiſe of Fluxions, art, 290, 291.

Dr. Reid, in his "Inquiry into the Human Mind, on the Principles of Common Senſe," endeavours to obviate the difficulties ſuggeſted by Berkeley, by overturning the ſyſtem of ideas eſtabliſhed by Mr. Locke. According to his theory, it is abſurd to deduce from ſenſation the firſt origin of our notions of external exiſtence, of ſpace, motion, and extenſion, and all the primary qualities of bodies; they have, he ſays, no reſemblance to any ſenſation, or to any operation of our minds, and therefore they cannot be ideas either of ſenſation or reflection; nor can he conceive how extenſion, or any image of extenſion, can be in an unextended and indiviſible ſubject like the human mind.

Extension, in the *Ancient Muſic*, according to Ariſtoxenus, was one of the four parts of the melopœia, which conſiſted in ſuſtaining certain ſounds longer than their quantity ſtrictly required. We call theſe binding-notes, and ſometimes perhaps tempo rubato. See Compass.

Extension *of Fractured Limbs.* See Fracture.

EXTENSOR, in *Anatomy*, a name given to thoſe muſcles which have the uſe of extending or making ſtraight thoſe parts to which they are attached.

Extensor *brevis digitorum pedis*; calcaneo-ſus-phalangettien commun, is a thin and flat muſcle, placed on the ſuperior or convex ſurface of the foot. Poſſeſſing a ſomewhat quadrilateral figure behind, it divides into four flat tendons in front. It ariſes from the upper and front part of the os calcis, and from the ligament which connects that bone to the aſtragalus. Thence its fibres are continued obliquely forwards and inwards, and divide into four ſecondary faſciculi, (of which the two innermoſt are the largeſt,) giving origin to the ſame number of tendons; which, in paſſing over the metatarſus, croſs thoſe of the extenſor longus, and terminate in the toes. The firſt, on the inſide, is attached to the upper ſurface of the metatarſal extremity of the firſt phalanx of the great toe; the three ſucceeding tendons become intimately attached to the external edge of the correſponding tendons of the extenſor longus, and are connected at the firſt joints of the toes, as well as thoſe of the latter muſcle, with the tendons of the lumbricales and interoſſei. They extend over the ſecond phalanges, and are inſerted in the third.

Covered on its external ſurface by the tendons of the extenſor longus and peroneus tertius, and by the aponeuroſis of the back of the foot, this muſcle lies upon the anterior phalanx of the tarſus, upon the metatarſus, and the phalanges.

It extends and elevates all the phalanges of the toes, at the ſame time turning them rather outwards.

Extensores *carpi radiales.* See Carpi.

Extensor *carpi ulnaris.* See Carpi.

Extensor *communis digitorum manus*; epicondylo-ſus-phalangettien commun; extenſive digital; a muſcle belonging to the fingers, ſituated on the poſterior or dorſal ſurface of the fore-arm, hand, and fingers; elongated, ſomewhat rounded and fleſhy above, and divided into four tendons below.

It ariſes above, by means of a tendon common to it with the ſurrounding muſcles, from the external condyle of the humerus; is connected internally to a tendinous partition, which ſeparates it from the extenſor of the little finger, externally to a ſhorter ſeptum placed between it and the extenſor carpi radialis brevior, and poſteriorly to the faſcia of the fore-arm. The fibres, uniting together obliquely from theſe origins, form a muſcle, at firſt thin, and afterwards more conſiderable, which is divided, towards the middle of the fore-arm, into four portions, united at firſt by cellular ſubſtance, then ſeparating, and giving origin to the ſame number of tendons. Theſe at firſt are connected by a looſe cellular ſubſtance, paſs together with the tendon of the indicator under the annular ligament at the back of the wriſt, and in a ſuperficial groove of the radius, ſurrounded by a burſa mucoſa, then diverge towards the fore fingers, and become completely flattened. They are often ſplit longitudinally, and are united to each other, at the back of the hand, by croſs ſlips of tendon and their aponeuroſes. At the firſt joints of the fingers the broad thin tendons of the extenſor communis are joined, on either ſide by the tendinous expanſions of the lumbricales and interoſſei, and completely cover the articulation. They divide, at their extremities, into three portions, the middle of which are inſerted in the ſecond phalanges of the fore-fingers; while the lateral diviſions, running along the ſides of theſe phalanges, are inſerted cloſe together into the third.

This muſcle is covered by the aponeuroſis of the fore-arm, the annular ligament and ſkin. It covers the ſupinator radii brevis, the extenſors of the thumb and fore-finger, the carpus, metacarpus, interoſſei muſcles, and poſterior ſurface of the phalanges.

The annular ligament at the back of the fore-arm conſiſts of a broad, thin, and flat, but ſtrong fibrous expanſion, extended from the outer part of the carpal extremity of the radius, over all the extenſor tendons at the back of the wriſt, and connected to the end of the ulna, and to the os piſiforme. It confines the tendons to the ſurface of the bones. Thoſe of the common extenſor are ſurrounded, as they paſs under it, by a ſynovial membrane, in which we may diſtinguiſh a cavity containing the membranes completely iſolated, and a ſuperior and inferior cul de ſac, where the membrane is reflected over the tendons. The ſynovial membranes of the firſt joints of the fingers are cloſely connected to the tendons of the extenſor communis, where they paſs over thoſe joints.

This muſcle extends the different joints of the fingers; and afterwards, or if the fingers are bent by their flexors, it extends the wriſt upon the fore-arm.

Extensor *indicis*. See Indicator.

Extensor *longus digitorum pedis*; peroneo-tibi-ſus-phalangettien commun; grand extenſeur; is a long, thin muſcle, flattened laterally, and placed at the outer and anterior part of the leg, and upper part of the foot. It ariſes above from the external tuberoſity of the tibia, from a ſmall aponeurotic ſeptum which ſeparates it from the tibialis anticus, and from the anterior ligaments of the peroneo-tibial articulation; behind from five or ſix inches of the upper and anterior part of the fibula; before, at its upper part, from the aponeuroſis of the leg; and externally, from a broad aponeurotic ſeptum, which ſeparates it from the two peronei. The ſuperior fibres deſcend perpendicularly, the inferior ones more and more obliquely, to end in a common tendon at firſt concealed in the ſubſtance, but, from the middle of the leg, occupying the anterior edge of the muſcle. It divides into three or four portions, which paſs together behind the annular ligament: below which part we always ſee four ſeparate tendons diverging over the convexity of the foot, aſſuming a broad and flattened form, and croſſing the direction of the tendons of the extenſor brevis, in their paſſage to the four ſmaller toes. At the firſt joints of the toes theſe tendons are connected to thoſe of the extenſor brevis, and of the lumbricales and interoſſei, as in the hand, and they have ſimilar inſertions to thoſe of the extenſor communis digitorum, which ſee.

In the leg, this muſcle, on its inner ſurface, is ſeparated above by the anterior tibial veſſels from the tibialis anticus; lower down it is contiguous, on the ſame aſpect, with the extenſor proprius hallucis: externally it is in contact with the peronei; and the aponeuroſis of the leg covers it on the front. At the ankle it runs in a peculiar cavity of the ſtrong tranſverſe annular ligament, which binds it firmly down in its place. Here the tendons are ſurrounded by a ſynovial membrane. In the foot it is covered by the ſkin, and covers the extenſor brevis and phalanges.

This muſcle extends the toes, and afterwards bends the ankle joint. If the foot be fixed to the ground, it may either maintain the leg erect upon the foot, or carry it forwards.

Extensor *longus pollicis pedis*; or *proprius*; peroneo-ſus-phalanginien du pouce; thin, elongated and flattened in its form, it lies on the inſide of the preceding muſcle. It ariſes from the inner and anterior part of the fibula, and neighbouring portion of the interoſſeous ligament, for a ſpace of five or ſix inches, beginning about two inches below the upper end of the fibula. Its fibres paſs obliquely downwards and forwards, parallel to each other, and joining a tendon which runs along their anterior edge, conſtitute a ſingle penniform muſcle. The tendon goes behind the annular ligament, in a peculiar burſa mucoſa, runs along the inner edge of the metatarſus, and paſſing over the firſt, terminates in the ſecond phalanx of the great toe. Sometimes a ſmall portion of its tendon is inſerted in the firſt phalanx.

This muſcle is placed between the tibialis anticus, the anterior tibial veſſels and nerves being however interpoſed, and the extenſor longus digitorum. On the front it is covered by the aponeuroſis of the leg, the annular ligament, and the integuments. Its tendons lie on the lower end of the tibia, the tarſus, metatarſus, and phalanges of the great toe, and is cloſely connected to the ſynovial membrane of the firſt joint of that toe.

It extends the two joints of the great toe, and acts upon the foot in the ſame manner as the preceding muſcle.

Extensor *major pollicis*. See Extensores *pollicis*.

Extensor *minor pollicis*. See Extensores *pollicis*.

Extensor *oſſis metacarpi pollicis*. See Extensores *pollicis*.

Extensores *pollicis*; are three muſcles belonging to the three bones of the thumb.

Extensor *primi internodii*; extenſor oſſis metacarpi pollicis; abductor pollicis longus of Albinus; cubito-radi-ſus-metacarpien du pouce; grand abducteur du pouce; is a muſcle of an elongated, thin, and flattened form, ſituated obliquely on the back of the fore-arm. It ariſes above from the ulna, below the ſupinator radii brevis; from the interoſſeous ligament; and from the radius juſt below the inſertion of the ſupinator brevis. The fleſhy fibres unite together from theſe origins to form a flattened faſciculus at firſt ſmall, but afterwards larger, which croſſes the fore-arm obliquely from above downwards, and from the radial towards the ulnar ſide. Towards the lower extremity of the radius it terminates in a tendon, which runs in a ſmall groove on the outer ſide of the carpal extremity of the bone. Here it is ſurrounded by a hollow burſa, common to it with the tendon of the next muſcle. It is inſerted, generally by means of ſeveral more or leſs diſtinct portions, into the radial ſide of the carpal end of the firſt phalanx of the thumb. One of theſe portions is often connected with the abductor pollicis.

It is covered, in its fleſhy portion, by the extenſor carpi ulnaris, extenſor ſecundi internodii, extenſor proprius auricularis, and communis digitorum; and it covers the radius, ulna and interoſſeous ligament. Its tendon is covered by the aponeuroſis of the fore-arm, and covers the extenſores carpi, the radius, radial artery, and joint of the wriſt.

It extends the firſt bone of the thumb, when that has been bent towards the palm of the hand. It carries the thumb away from the other fingers; and it may move the whole hand towards the radius.

Extensor *ſecundi internodii*; extenſor minor pollicis; cubito-ſus-phalangien du pouce; is an elongated and ſlender muſcle, ſituated cloſe to the former, and lying on its ulnar edge. Ariſing from the interoſſeous ligament and radius, it croſſes the direction of the fore-arm, like the former, and forms a ſlender tendon, which cloſely accompanies that of the preceding muſcle. It paſſes along the firſt, and is inſerted in the ſecond phalanx of the thumb. It is covered by the extenſor tertii internodii, proprius auricularis, and digitorum communis, by the aponeuroſis of the fore-arm, and the integuments. It lies upon the bones of the fore-arm and the interoſſeous ligaments, the extenſores carpi radiales, the joint of the wriſt, and the firſt bone of the thumb. It extends the firſt and ſecond joints of the thumb, and carries it into the ſtate of abduction. It may draw the whole hand towards the radius.

Extensor *tertii internodii*; extenſor major pollicis; cubito-ſus-phalangettien du pouce; is an elongated and ſlender muſcle, placed cloſe on the ulnar edge of the former, and following the ſame general direction. It ariſes from the middle third of the poſterior ſurface of the ulna, and a very little from the interoſſeous ligament; and croſſes the fore-arm obliquely towards the thumb. Surrounded by a hollow burſa, it runs along a peculiar groove of the radius, being placed about an inch on the ulnar ſide of the preceding tendons. It paſſes along the ulnar ſide of the firſt phalanx of the thumb; is connected with the inſertion of the preceding tendon in the ſecond phalanx, and terminates in the third. Situated at its origin between the bones of the fore-arm and interoſſeous ligament, and the extenſor communis, proprius auricularis, and carpi ulnaris, it afterwards runs in its peculiar groove: it is then ſub-cutaneous, and lies on the extenſores carpi, joint of the wriſt, and bones of the thumb. It extends all the joints of the thumb, and at the ſame time rather carries it towards the fingers. It will alſo act as an extenſor of the wriſt.

Extensor *proprius auricularis*, or digiti minimi; epicondylo-ſus-phalangettien du petit doigt; is a thin, ſlender, and elongated muſcle, ſituated in the firſt or ſuperficial layer of the back of the fore-arm, and placed cloſe along the ulnar ſide of the extenſor digitorum communis. It ariſes above by means of the common tendon, from the external condyle of the humerus; on the outſide, from a ſeptum, which ſeparates it from the extenſor communis; on the inſide, from one interpoſed between it and the flexor carpi ulnaris; and behind, from the aponeuroſis of the fore-arm. It gives origin to a ſlender tendon, which paſſes in a ſeparate canal of the annular ligament, and forming the tendon which the little finger receives from the extenſor communis, is inſerted together with it into that finger. On the fore-arm, this muſcle is covered by the faſcia, and covers the ſupinator brevis, the extenſors of the thumb, and the indicator. The extenſor communis lies on its outſide, and the extenſor carpi ulnaris on the inſide. Its tendon is ſurrounded by a tendinous ſheath, lined with a ſynovial membrane, at the wriſt; and afterwards is covered by the integuments lying on the laſt metacarpal bone, and on the phalanges of the little finger. It extends the little finger, and afterwards moves the wriſt in the ſame direction; it will carry the little finger rather in the direction of abduction.

Extensor *proprius pollicis pedis*. See Extensor *longus pollicis pedis*.

Extensor *tarſi minor*, a name given by Douglas to the plantaris, which ſee.

Extensor *tarſi ſuralis*, or magnus; a name under which Douglas claſſes the gaſtrocnemius and ſoleus. See thoſe words

EXTENT, or Extendi Facias, in *Law*, ſometimes denotes a writ or commiſſion to the ſheriff for the valuing of lands and tenements; ſometimes the act of the ſheriff or other commiſſioner upon this writ; and ſometimes the eſtimate or valuation of lands, *per proprios viros*; which, when taken at the utmoſt value or extent, furniſh our extended, or rack-rents. Fleta. lib. ii.

This is a ſpecies of *execution* (which ſee) upon ſome proſecutions given by ſtatute; as in the caſe of recognizances or debts acknowledged on ſtatutes-merchant, or ſtatutes-ſtaple; upon forfeiture of which, the body, lands, and goods may be all taken at once, to compel the payment of the debt. And by ſtatute 33 Hen. VIII. c. 39. all obligations made to the king ſhall have the ſame force, and of conſequence the ſame remedy to recover them, as a ſtatute-ſtaple; though, indeed, before this ſtatute, the king was entitled to ſue out execution againſt the body, lands, and goods of his accountant or debtor. (3 Rep. 12.) And his debt ſhall, in ſuing out execution, be preferred to that of every other creditor, who hath not obtained judgment before the king commenced his ſuit. The king's judgment alſo affects all lands, which the king's debtor hath at or after the time of contracting his debt, or which any of his officers, mentioned in the ſtatute 13 Eliz. c. 4. hath at or after the time of his entering on the office; ſo that, if ſuch officer of the crown alienes for a valuable conſideration, the land ſhall be liable to the king's debt, even in the hands of a *boná fide* purchaſer; though the debt due to the king was contracted by the vendor many years after the alienation. (10 Rep. 55, 56.) Whereas judgments between ſubject and ſubject reverted, even at common law, no farther back than the firſt day of the term in which they were recovered, in reſpect of the lands of the debtor; and did not bind his goods and chattels, but from the date of the writ of the execution: and now, by the ſtatute of frauds, 29 Car. II. c. 3. the judgment ſhall not bind the land in the hands of a *boná fide* purchaſer, but only from the day of actually ſigning the ſame; which is directed by the ſtatute to be punctually entered on the record; nor ſhall the writ of execution bind the goods in the hand of a ſtranger, or a purchaſer (Skin. 257.); but only from the actual delivery of the writ to the ſheriff or other officer, who is therefore ordered to endorſe on the back of it the day of his receiving the ſame. Blackſt. Comm. book iii.

EXTENUATION, the act of diminiſhing or leſſening the bulk or ſubſtance of a thing, eſpecially of the human body. Fevers, agues, long abſtinences, &c. occaſion great extenuations or emaciations.

Extenuation is alſo a figure in *Rhetoric*, oppoſite to the hyperbole. The Greeks call it λιτότης.

EXTERIOR *Polygon*, *Talus*. See the ſubſtantives.

EXTERMINATION, formed of *ex* and *terminus*, *boundary*, the act of extirpating, or totally deſtroying a people, race, family, &c.

The Jews have been exterminated out of Portugal, the Moors out of Spain, the Albigenſes out of France, &c. Philip the Fair of France, to be revenged on the Knights Templars, took a reſolution, in 1307, to exterminate them.

Extermination, or *Exterminating*, in *Algebra*, is uſed for taking away. Thus algebraiſts ſpeak of exterminating ſurds, fractions, and unknown quantities out of equations. See Maclaur. Algebr. part i. chap. 12, where we have ſome general theorems for the exterminating unknown quantities in given equations. See Equation.

EXTERNAL, or Exterior, a term of relation applied to the ſurface or outſide of a body; or that part which appears or preſents itſelf to the eye, touch, &c. In which ſenſe it is oppoſed to *internal* or *interior*.

The ſenſes are divided into external, which are thoſe whereby we perceive ideas, or have the perception of external objects; as ſeeing, hearing, &c. and internal. See Sense.

External is alſo uſed to expreſs any thing that is without-outſide a man, or that is not within him, and particularly in his mind. In which ſenſe we ſay external objects, &c.

The exiſtence of an external world, *i. e.* of bodies and objects out of the mind, is a thing which has been greatly called in queſtion by Dr. Berkeley and others. See EXISTENCE, BODY, and QUALITY.

EXTERNAL *Angles*. See ANGLES, *external*.

EXTERNAL *Denomination, Ear, Modes, Place*. See the ſubſtantives.

EXTERNUS AURIS, in *Anatomy*. See EAR.

EXTERNUS *Cubitæus*. See CUBITÆUS.

EXTERNUS *Duverni*, a name given by Douglas to one of the muſcles of the ear, called by Cowper and others obliquus auris, and by Albinus externus mallei. See EAR.

EXTERNUS *Gaſtrocnemius, Iliacus*. See the ſubſtantives.

EXTERNUS *Mallei*. See EAR.

EXTERNUS *Orbiter, Pterigoideus, Vaſtus, Rectus Capitis*, See the ſeveral articles.

EXTINCTION, the act of extinguiſhing, that is, of putting out, or deſtroying, fire, flame, or light.

The Ariſtotelians account for the extinction of fire from the principle of contrariety; thus, ſay they, water puts out fire, becauſe the qualities of water are contrary to thoſe of fire, the one being cold and moiſt, and the other hot and dry. But how far this will go, may appear hence, that fire is extinguiſhed by hot water as readily as cold; nay, even by oil, earth, &c.

Some of the moderns offer two more plauſible cauſes of extinction; *viz.* diſſipation, as when the next immediate fuel of the flame is diſperſed and blown off by too forcible a wind; and ſuffocation, when it is ſo compreſſed, that its free motion cannot be maintained; as happens upon throwing water, &c. thereon. Various preparations and engines have been contrived for extinguiſhing accidental fires. See FIRE.

Boerhaave denies that there is properly any ſuch thing as extinguiſhing of fire; it is a body *ſui generis*, of an immutable nature, and we can no more extinguiſh or deſtroy it than we can create it.

EXTINCTION, in *Chemiſtry* and *Pharmacy*, is when a metal, mineral, or the like body, after having been heated red-hot in the fire, is plunged in ſome fluid, either to ſoften or temper its acrimony, as tutty in roſe-water; or to communicate its virtue to the liquor, as iron or ſteel to common water; or, laſtly, to give it a temper, as in the extinction of ſteel in water, or ſome other preparation.

EXTINGUISHER, SELF-ACTING, is a contrivance whereby a candle can be extinguiſhed at any given time after being lighted. There are ſeveral ways by which this can be effected. The moſt ſimple is placing the candle in a veſſel of water, with ſuch a length above the ſurface as will burn as long as a light is wanted; of courſe when the candle burns down to the water it will be extinguiſhed.

Figs. 10 and 11, *Plate* XII. *Miſcellany*, repreſent two neat mechanical contrivances for the above purpoſe; in *fig.* 10, *a a* is a braſs clip, formed of two pieces, and jointed together by the pin, *b*, by means of a ſliding ring, *d*; this clip can be cloſed round the candle ſo as to fix firmly thereto; the pin, *b*, has a joint in the upper end to receive a crooked lever, *e*, which has a conical extinguiſher faſtened at the other end of it. This extinguiſher is held up from falling upon the candle, by means of a ſmall wire, *f*, which is bent ſideways at the end, and thruſt into the candle, at the place where it is intended to be put out; as the tallow is conſumed, it becomes ſo ſoft as to be unable to ſuſtain the preſſure of the wire, *f*, which therefore flies forward, and the extinguiſher falls upon the candle. It muſt be obſerved that the wire, *f*, muſt only be put into the tallow, but not in the wick, as it might not then fall down quickly.

Fig. 11 is another extinguiſher, invented by Mr. J. J. Hawkins, and placed in his muſeum of mechanical inventions: *a a* is a pair of nippers, made of tinned iron plate, and jointed in the middle; between the outer ends a piece of watch-ſpring is fixed, which cauſes the ends, *b*, to cloſe upon the candle, and thus hold the extinguiſher on the candle. The centre-pin of the joint is long enough to ſerve for the centre of another clip, *b b*, which is exactly ſimilar to the lower one, except that inſtead of the bow to embrace the candle, two wires, *c*, *e*, are fixed to the ends, to ſhut the extinguiſher, which is compoſed of two flat plates, *f*, *f*, which open and ſhut upon the joint, *g*. The ſpring between the ends of the nippers, *b*, *b*, has a conſtant tendency to cloſe the extinguiſher, but is prevented from ſhutting by the candle. When the candle burns away, it becomes ſoft at the place where the extinguiſher bites the ſpring, then ſhuts it up, and puts out the light.

EXTINGUISHMENT, in *Law*, is uſed for a conſolidation. Thus, if a man, having a yearly rent due to him out of my lands, afterwards purchaſe the ſame lands; both the property and rent, becoming conſolidated, or united in one poſſeſſor, the rent is ſaid to be extinguiſhed.

So, where a man has a leaſe for years, and afterwards buys the property, there is a conſolidation of the property, and an extinguiſhment of the leaſe.

But if a man have an eſtate in land merely for life or years, and hath a higher eſtate in a fee-ſimple, in the rent, this rent is not extinguiſhed, but in ſuſpence for a time; for, after the term, the rent ſhall revive. (Terms de Ley.) See RELEASE.

So alſo, if there be lord meſne and tenant, and the lord purchaſe the tenancy, the meſnalty is extinct.

Likewiſe by purchaſing of lands wherein a perſon hath common appendant, the common is extinguiſhed. (Cro. El. 594.) A releaſe of common in one acre, is an extinguiſhment of the whole common. Shower's Rep. 350.

And where a perſon hath common of vicinage, if he incloſes any part of the land, all the common is extinct. (1 Brownl. 174.) If a man hath a highway appendant to land, and afterwards purchaſeth the land wherein the highway is, the way is extinct: though it is held, that a way of neceſſity to a market or church, or to arable land, is not ſo extinguiſhed. 11 Hen. VII. 25 Co. Litt. 155.

EXTINGUISHMENT *of a copyhold* takes place on any act of the copyholder's, which denotes his intention to hold no longer of his lord, and amounts to a determination of his will. (Hutt. 81. Cro. Eliz. 21. 1 Jon. 41.) As if a copyholder in fee accepts a leaſe for years of the ſame land from the lord, or accepts an aſſignment of a leaſe made to another from the leſſee, his copyhold is extinct. (Moor. 184. 2 Co. 166. Godb. 11. 101.) A copyhold eſtate is extinct whenever it becomes not demiſeable by copy. Coke's Copyholder, 62. See COPY-HOLD.

EXTINGUISHMENT *of debt* happens in a variety of caſes. Thus, if a creditor accepts a higher ſecurity than he had before, or accepts a bond for a legacy, the firſt debt or legacy is hereby extinguiſhed.

EXTINGUISHMENT *of liberties*. If liberties and franchiſes granted by the king, ſuch as felon's goods, waifs, ſtrays, wrecks, &c. (9 Rep. 25.) come again to the crown, they are extinct in the crown, and the king is ſeiſed of them *jure coronæ*: but if liberties of fairs, markets, or other franchiſes, and juriſdictions, be erected, and created by the king, they will not be extinguiſhed, nor their appendances ſevered from the poſſeſſion. 9 Rep. 25.

EXTINGUISHMENT *of ſervices*. If the lord purchaſes or, accepts any part of the tenancy, out of which an entire ſervice is to be paid or done, the ſervice becomes thereby extinct; unleſs it be for the public good, or homage and fealty, which are not ſubject to extinguiſhment. (6 Rep. 1. 105. Co. Litt. 149.) If the lord and another perſon do purchaſe the lands out of which he is to have ſervices, they are extinct; alſo by ſeverance of the ſervices a manor may be extinguiſhed. Co. Litt. 147. 1 And. 257. See Tenure.

Extinguishment *of ways*. See Extinguishment.

EXTIRPATION, formed of *ex* and *ſtirps*, *root*, the act of pulling up, or deſtroying, a thing to the very roots.

Among the prayers of the Romiſh Jubilee, there is one for the extirpation of hereſy.

Extirpation. This word, in *Surgery*, ſignifies the eradication of any diſeaſe, tumour, &c. by ſome manual operation, whether done with a cutting inſtrument, with cauſtic, with a ligature, or any other means.

Thus, the generality of tumours are extirpated with a knife; but ſome, which claſs as excreſcences, or warts, are frequently extirpated with cauſtic, or with the ligature. The extirpation of polypi in the noſe is, for the moſt part, accompliſhed with forceps, by which ſuch tumours are pulled, or rather twiſted off.

The art of extirpating encyſted tumours with adroitneſs conſiſts in diſſecting the parts, ſurrounding the tumour, without wounding the cyſt. If the latter accident occur, the contents frequently flow out, the cyſt collapſes, and the continuance of the diſſection is attended with more difficulty. It is a great point to remove every particle of the cyſt, and, hence, it is ſatisfactory to take it out entire, that is, without wounding it. When any portion remains behind, the wound will frequently not heal, in conſequence of fungous granulations, ariſing from the diſeaſed part. Unleſs the ſwelling be large, a ſingle inciſion through the ſkin is ſufficient; but, in other inſtances, it is advantageous to make two cuts in this manner ( ); firſt, becauſe it facilitates the removal of the tumour; ſecondly, becauſe it prevents a redundance of ſkin, which would take place, if none were removed, and would greatly retard the cicatrization of the wound.

After the operation, the edges of the wound are to be brought together with ſticking plaſter, and a compreſs and bandage are to be applied.

When the breaſt is affected with any diſeaſe of an incurable nature, the ſurgeon can ſometimes extirpate the malady by cutting away the whole of the diſeaſed parts.

If the diſeaſe be of a ſcirrhous or malignant nature, ſome particularity in the mode of operating is requiſite. The ſurgeon ought, in this caſe, not to be content with merely removing parts, which are palpably and viſibly diſeaſed, but he ſhould alſo endeavour to remove a certain quantity of the ſubſtance, which is in the immediate circumference of the diſeaſe. In ſcirrhus, every ſurgeon knows the propenſity of the ſkin to be affected, and the frequent extenſion of white morbid bands into the ſurrounding adipoſe ſubſtance. Theſe facts greatly confirm the propriety of making a free removal of the ſkin, whenever it is in the leaſt diſcoloured, puckered, adherent to the ſwelling beneath, or in any way altered; and of taking away a good deal of the fat, in which ſcirrhous tumours are ſometimes involved. When there are no reaſons for ſuppoſing the diſeaſe of the breaſt to be any thing elſe than a mere ſarcomatous enlargement, the removal of the ſkin muſt certainly be conſidered unneceſſary. When cancer recurs, the ſkin is the firſt part in which it uſually makes its appearance, and the ſkin of the nipple in particular. Hence, many ſurgeons always make it a rule to remove the latter part, when it is judged proper to take away any of the integuments.

The operation is uſually performed as the patient is in a ſitting poſture, well ſupported by pillows and aſſiſtants.

The pectoral muſcle is to be made tenſe by keeping the arm back, by means of a ſtick, placed tranſverſely behind the back, in front of the two arms.

If none of the integuments are to be removed, a ſtraight inciſion is to be made through them; the tumour is to be regularly diſſected all round from the circumjacent parts; and, laſtly, its baſe is to be detached from its connections, from above downward, till the whole is ſeparated.

This is the mode of removing all ſimple tumours, which are not of a malignant nature, and which are not of an immenſe ſize.

When the tumour is of a malignant nature, and adherent to the ſkin and pectoral muſcle beneath, the operator is to remove, at leaſt, an inch or two of the fat on every ſide of the diſeaſe. The portion of the ſkin intended to be taken away muſt be included in two ſemi-circular inciſions, which meet thus ( ) at their extremities; and when the baſe of the tumour is to be detached, the ſurface of the pectoral muſcle, wherever it is adherent to the tumour, is alſo to be removed.

It is ſufficiently obvious, that the advantage of making the inciſion in the above manner conſiſts in enabling the ſurgeon to bring the edges of the wound together after the operation, ſo as to form a ſtraight line, and unite by the firſt intention.

The mere magnitude of a tumour frequently renders it highly judicious to take away a portion of the ſkin in the above method. If ſome were not removed, the diſſection of the tumour would be exceedingly tedious; and, after the operation, the looſe undiſtended ſkin would lie in folds, and form, as it were, a large pouch for the lodgment of matter.

The tumour being removed, the ſurgeon ſhould examine the interior of the wound, in order to aſcertain that no indurated part is left behind. If any hardneſs ſhould be felt, it is proper to remove it. The ſurgeon ſhould alſo examine the ſurface of every ſcirrhous tumour, immediately after it is taken out, for the purpoſe of knowing whether any of the white bands, ſhooting into the ſurrounding fat, have been divided; for, in this caſe, ſome portions have been left behind, and ought to be taken away. Their ſituation may eaſily be known, by conſidering the poſition of the tumour before the operation.

When the diſſection of a ſwelling will occupy a conſiderable time, it is always judicious practice to tie every large artery as ſoon as it is divided. This remark is not meant to comprehend veſſels of ſuch a diameter, that though they bleed when firſt cut, they do not emit blood afterwards, ſo as to require a ligature. It was Default's invariable method, in cutting out tumours, to tie every large artery before he continued the diſſection.

When a tumour of the breaſt has been entirely detached, and the hemorrhage ſuppreſſed, the ſtick confining the arm backward is to be removed. Then if there are any diſeaſed glands in the axilla, it is a very excellent plan to tie the pedicles, by which they are attached on the ſide towards the axilla, before attempting to cut the tumours completely away. It would be extremely difficult, after taking off the gland, to tie the little ſhort artery which enters the ſwelling, almoſt immediately after it has quitted one of the thoracic arteries. The bleeding alſo, in conſequence of the ſhortneſs of the veſſel, and vicinity of its orifice to the thoracic arteries, would be exceedingly profuſe, ſeeming rather to ariſe from a wound of the latter veſſels than of a ſmall branch.

The celebrated Deſault uſed to purſue the practice above recommended ; and ſir Charles Blicke has long been in the habit of obſerving the ſame rule, in the numerous operations which he has performed with the utmoſt benefit to the afflicted, and well deſerved honour to himſelf.

When the operation is finiſhed, the ſkin of the wound is to be relaxed, and the edges of the inciſion brought together with ſtrips of adheſive plaſter. Proper compreſſes and bandages are next to be applied. Should the operation have been the removal of a diſeaſed breaſt, the neareſt arm ſhould be kept completely at reſt in a ſling, as whenever it moves, it occaſions a diſturbance of the pectoral muſcle, and, of courſe, of the wound. (Firſt lines of the "Practice of Surgery," by Samuel Cooper.)

For the mode of extirpating a diſeaſed teſtis, ſee CASTRATION.

The method of effecting the extirpation of polypi is to be deſcribed in the article POLYPUS.

Some obſervations are offered, under the head EXOSTOSIS, on the ſubject of extirpating tumours of the bones. The way in which a diſeaſed eye ought to be cut out, will be hereafter explained. See EYE, *Extirpation of*.

For an account of the plan of extirpating certain excreſcences, ſee EXCRESCENCE.

EXTIRPATIONE, in *Law*, a judicial writ, either before or after judgment, that lies againſt a perſon, who when a verdict is found againſt him for land, &c. doth maliciouſly overthrow any houſe, or extirpate any trees upon it. Reg. Jud. 13. 56.

EXTISPEX, formed of *exta*, and *ſpicere*, of *ſpicio*, or *inſpicere*, *I view*, *conſider*, in *Antiquity*, an officer who viewed and examined the intrails of victims ; in order to draw preſages from them as to futurity.

This kind of divination, called extiſpicium, was much in vogue throughout Greece, where there were two families, the Jamidæ and Clytidæ, conſecrated, or ſet apart, peculiarly for it.

It appears to have been very ancient, and was probably derived from the ancients. Vitruvius, cap. 4. lib. i. gives the following plauſible account of its origin. He ſays that the ancients inſpected the livers of thoſe animals which frequented the places where they intended to build or encamp ; and if they commonly found that the liver, to which they attributed ſanguification, was injured, they concluded that the waters and nouriſhment collected near ſuch places were not wholeſome.

In Italy, the firſt extiſpices were the Etrurians or Tuſcans ; among whom, likewiſe, the art was in great repute. Lucan gives us a fine deſcription of one of theſe operations in his firſt book.

EXTORTION, in *Law*, denotes generally any oppreſſion under colour of right ; and it is uſually applied to ſignify an illegal manner of wreſting any thing from a man, either by force, menace, or authority : *e. g.* if an officer, by terrifying another on pretence of his office, or "by colour of his office," takes more than his ordinary fees or dues, he commits, and is indictable for, extortion.

So the exacting of unlawful uſury, winning by unlawful game, and, in fine, all taking of more than is juſtly due, by colour or pretence of right, as exceſſive tolls in millers, exceſſive prices of ale, bread, victuals, wares, &c. come under extortion.

Crompton ſays, that wrong done by any man is properly a treſpaſs, but exceſſive wrong is extortion ; which is moſt properly applicable to ſheriffs, mayors, bailiffs, and other officers, who, by colour of their office, greatly oppreſs and wrong the king's ſubjects, by taking exceſſive reward, or fees, for executing their office : and extortion has been deemed more odious than robbery, becauſe it carries an appearance of truth ; and is often accompanied with perjury in officers, &c. by violating their oaths of office. The diſtinction between bribery and extortion ſeems to be this : the former offence conſiſts in the *offering* a preſent, or receiving one if offered ; the latter, in *demanding* a fee, or preſent, by colour of office. Extortion by the common law is ſeverely puniſhed, on indictment, by fine and impriſonment, and removal of officers from the offices in which the crime was committed. By the ſtat. 3 Edw. I. inferior officers of juſtice, &c. guilty of extortion, are to render by c. 26. double, and by c. 30. treble, value ; and there are divers other ſtatutes for puniſhing extortions of ſheriffs, bailiffs, gaolers, clerks of the aſſiſe, and of the peace, attornies and ſolicitors, &c. ſtats. 23 H. VI. c. 7 & 9. 33 H. VIII. c. 24. 29 Eliz. c. 4. 1 Jac. I. c. 10. 9 & 10 W. III. c. 41. 10 & 11 W. III. c. 23. 3 Geo. I. c. 15. 17 Geo. III. c. 26. § 6. In caſes of extortion, there muſt be a poſitive charge, that the charged perſon did it *extorſivé*, or *colore officii*. The place where it was committed muſt be ſet down in the declaration ; the ſum extorted particularly ſpecified, and the indictment or information muſt ſtate the full particulars by ſpecifying the time, &c. Againſt attornies for extortion, action may be brought, and the party aggrieved ſhall have treble damages and coſts ; but information will not lie on the ſtat. 3 Jac. I. c. 7. Sid. 434. 4 Nelſ. 822.

EXTRA-*Conſtellary Stars*. See SPORADES.

EXTRA-*judicial*, ſomething done out of the proper court, or the ordinary courſe of law. As when judgment is given in a cauſe, or caſe, not depending in that court where ſuch judgment is given, or wherein the judge has no juriſdiction.

EXTRA-*mundane ſpace*, is the infinite empty void ſpace, which is by ſome ſuppoſed to be extended beyond the bounds of the univerſe, and conſequently in which there is really nothing at all.

EXTRA-*parochial*, a place out of the bounds of any pariſh ; or privileged and freed from the duties of a pariſh.

EXTRACT, in *Chemiſtry*. The term extract, as uſed in chemical nomenclature, has been borrowed from the pharmaceutical diſpenſatories, where it has long been applied to a great variety of ſubſtances which have little other agreement than in the mode of preparation, which conſiſts in extracting by water, or any other menſtruum, the ſoluble part of certain parts of vegetables, and inſpiſſating this ſolution by heat to a thick conſiſtence, or ſometimes to entire ſolidity.

The term extract, therefore, in its original and pharmaceutical ſenſe, only refers to the mode of preparation, and not to the nature of the ſubſtance prepared ; and hence much confuſion and uncertainty have prevailed in the attempts of chemiſts to define the nature of the ſubſtance to which this term ſhould in ſtrictneſs be limited.

All the pharmaceutical extracts are extremely compounded, for being prepared either by water or alcohol, of courſe every thing ſoluble in theſe liquids would be confounded in the general maſs. Hence we find in one or other, and ſometimes in a ſingle extract, mucilage, ſugar, tannin, gallic acid, reſin, gluten, ſeveral neutral ſalts, and other ingredients. But along with theſe there always is found a conſiderable quantity of a brown tenacious ſubſtance, often with a bitter taſte, and poſſeſſing a number of chemical properties, which entitle it to be conſidered as a peculiar ſubſtance, and to which the term extract, or extractive principle, has been given.

The diſtinguiſhing properties of this ſubſtance have been laid down with much ability by Vauquelin, in his memoir on the extractive principle (Journal de Pharmacie, p. 132.) and in his reſearches on the ſap and native juices of trees (An. Chem. tom. 31.) and alſo by Fourcroy in an elaborate and excellent analyſis of the cinchona of St. Domingo. An. Chem. tom. 8 & 9.

We ſhall firſt notice the experiments of Vauquelin, which being made on the native juices of plants, the extract already in ſolution, and unaltered by the heat requiſite in artificial decoction, is probably in a purer ſtate.

When the ſap of any tree is firſt drawn it is always colourleſs, or nearly ſo, but when inſpiſſated by heat, however moderate, it always aſſumes a brown colour, and in the proceſs of evaporation a certain though ſmall quantity of pulverulent brown inſoluble matter falls down. If this is collected ſeparately before the juice is entirely inſpiſſated, and treated with muriatic acid, one portion diſſolves with effervеſcence, and is found to be chiefly carbonat of lime, and an inſoluble part remains, which is conſidered by this excellent chemiſt as extract altered and oxygenated during the evaporation. If the concentrated ſap is now ſlowly evaporated to dryneſs, it yields a brown extract, ſtrongly deliqueſcent, and of a pungent ſaline taſte. This entire extract is always extremely compounded, containing in fact all the ſoluble ingredients of the original juice. Gallic acid, when preſent, is detected by a ſolution of iron; tannin, by a ſolution of iſinglaſs; ſalts of lime, by oxalic acid; ſugar, by the taſte, and by its ſoon acquiring the vinous fermentation. The entire extract alſo always contains acetous acid, partly in exceſs and partly united both to lime, potaſh, and ammonia, and hence when a few drops of ſtrong ſulphuric acid are poured upon any extract, copious vapours of pungent acetic acid are given out; and if this is done with large quantities, and in cloſe veſſels, acetic acid may be obtained pure. It is probably owing to the preſence of theſe neutral acetites, that all the inſpiſſated native juices attract moiſture ſtrongly from the air, and hence too their great diſpoſition, to mould and change by keeping.

Ammonia alſo is detected in moſt inſpiſſated juices of plants by the pungent vapours of this alkali, that are perceived on the addition of quick-lime, but in the natural ſtate the ammonia is more than neutralized by the acetous acid, as all the ſoft extracts redden betimes.

Extractive matter (meaning by this term the pure extract) appears to form a great portion of the colouring matter of vegetables. If to any liquid containing extract a ſolution of alum be added, a copious coloured inſoluble precipitate is produced, conſiſting chiefly of alumine in intimate combination with extractive matter, and the ſupernatant liquor remains clear and nearly colourleſs. The ſame proceſs takes place in dyeing, the alum being firſt fixed on the cloth as a *mordant*, as it is called. The ſolutions of tin poſſeſs this power of precipitating coloured extract as an inſoluble powder in a ſtill more ſtriking manner. That of the other metallic ſalts produce a ſimilar precipitate of extract, combined with the metallic oxyd.

The experiments of Fourcroy on the cinchona have been detailed at length under that article, to which we refer our readers. It may be obſerved in this place, that the facts relative to the ſubject of extract were, ſhortly, that the decoction of cinchona during evaporation depoſited a quantity of black matter, inſoluble in cold water, but which moſtly was diſſolved in alcohol, leaving however a portion of a red powder of a peculiar nature, which the author of the experiments conſiders as extractive matter, changed by union with oxygen, and thereby rendered inſoluble in water or alcohol. The appearance of this powder, and its inſolubility in water, might at firſt lead to the ſuppoſition that it was reſin, but its equal inſolubility in alcohol refutes this idea.

The preciſe nature of this inſoluble matter, which is depoſited on the evaporation of all vegetable infuſions or decoctions, is hitherto not known, and ſeveral objections to the opinion of its being merely *oxygenated extract* may be adduced, which we have already detailed under the article Cinchona.

On the whole, however, we may ſafely admit, that there is a peculiar ſubſtance found in almoſt all ſoluble matter of vegetables, and particularly in the common circulating juices, to which the term extract, or pure extractive principle, has been given, and which has the following diſtinguiſhing properties.

In its natural ſtate in the ſap of trees it is colourleſs, or nearly ſo; but when the ſolution is heated and inſpiſſated, it always acquires a deep colour, which is generally brown or fawn, with various ſhades, and by the ſame proceſs its ſolubility in cold water is diminiſhed.

It is in its natural ſtate equally ſoluble in alcohol as in water, by which circumſtance it is diſtinguiſhed both from pure mucilage and reſin.

It is inſoluble in ether.

It has a very ſtrong affinity with alumine, and with metallic oxyds, and when combined with ether it becomes inſoluble in water, alcohol, and many other menſtrua. By deſtructive diſtillation it is reſolvable into carbon, oxygen, and hydrogen, and a ſmall proportion of azot.

Much variety is found in the properties of ſmell, taſte, and colour, in the various extracts, and we are ſtill totally ignorant how far theſe varieties may depend on other admixtures, or whether there are different ſpecies of extract; and in general we may add that this ſubſtance appears to be one which moſt eaſily enters into intimate combination with all the other ſoluble vegetable principles, and, conſequently, can hardly by any known means be obtained pure, as it exiſts in the vegetable itſelf, and unchanged by the proceſſes of analyſis.

Extract, in *Pharmacy*. The greater number of pharmaceutical extracts are made by boiling the ſubſtance (in coarſe powder) in water, ſtraining the decoction, boiling it down till it is conſiderably concentrated, then gently drying the reſidue in a ſtove, or ſlow oven, to the requiſite conſiſtence.

A few of the extracts are made with alcohol inſtead of water, or with a mixture of the two; the ſubſtance being firſt digeſted with the alcohol, and the tincture, thus prepared, ſtrained off; the reſidue then boiled with water, and the decoction poured off, and both the decoction and tincture mixed, and evaporated ſlowly.

The purely ſpirituous extracts are alſo called reſins, and are always evaporated to dryneſs, when they remain hard brittle maſſes, with a vitreous fracture, reſoluble in alcohol, and in all eſſential characters reſembling the natural reſins.

In preparing the extracts by water the decoctions are uſually directed to be ſet aſide for ſome hours, that any ſediment may be depoſited, which laſt is to be rejected. But this is obviouſly a bad practice, as in many caſes much of the medicinal property of the plant reſides in this reſidue which ſubſides from the hot decoction on cooling.

Another ſpecies of extracts is the inſpiſſated juices of plants. Several powerfully medicinal plants, ſuch as the hemlock, are ſucculent vegetables, which, when ſtrongly expreſſed, yield a large quantity of a green turbid juice, which (after ſeparating the mere fragments of the plant) only requires to be inſpiſſated by a very gentle heat, to form the extract in the form in which it is uſed.

All the extracts, except thoſe made by alcohol, are liable to ſpoil by keeping. This is particularly the caſe with the inſpiſſated juice of the ſucculent plants, being compoſed of materials all extremely liable to fermentation, and being kept in a conſtant tendency to deliqueſcence by the neutral acetites which they contain. Therefore they muſt be kept in cloſe veſſels, but with every care the moſt important of them loſe their medicinal quality in no great length of time.

Extract, in *Matters of Literature*, denotes a ſhort abridgment of a book or paper, or of ſome of the matters thereof. The journals, nouvelles, bibliotheques, memoires, and other monthly reviews, or quarterly accounts of the affairs of learning, conſiſt principally of extracts of the moſt material paſſages, doctrines, &c. found in the ſeveral books publiſhed in that time.

Extract *ab Eccleſia*. See Restitutione *Extracti*.

EXTRACTA Curiæ, in our *Old Writers*, the iſſues or profits of holding a court, ariſing from the cuſtomary fees, &c.

EXTRACTION, in *Pharmacy* and *Chemiſtry*, an operation, whereby eſſences, tinctures, &c. are drawn from natural bodies. See Extract.

Extraction, in *Surgery*, is the drawing from, or out of the body, any thing fixed in it, as a thorn, or bullet, in the fleſh, a tooth from the jaw, &c. Surgeons ſpeak alſo of the extraction of a ſtone from the bladder, a cataract from the eye, foreign bodies from the œſophagus, extraneous ſubſtances from wounds, &c. For a deſcription of the methods of extracting a ſtone from the bladder, ſee Lithotomy.

The operation of extracting the cataract is explained in the article Cataract.

Extraction, or *Deſcent*, in *Genealogy*, denotes the ſtock, or family, which a perſon is deſcended from.

In ſome military orders, chapters, &c. a candidate muſt make proof of the nobility of his extraction before he is admitted.

Extraction *of Roots*, the method of finding the roots of given numbers, or quantities. See Root.

The ſquare, cube, and other powers of a number, or root, are formed by multiplying the given number into itſelf a greater or leſs number of times, as the power required is higher or lower. See Power.

This multiplication compounds the powers; and the extraction of the roots decompounds them again, or reduces them to their principles or roots. So that the extraction of the root is to the multiplication of the power, what the analyſis is to the ſyntheſis.

Thus, 4, multiplied by 4, produces 16; which is the ſquare of 4, or the factum of 4, by itſelf; and 16 multiplied by 4, makes 64, which is the cube of 4, or the factum of 4 by its ſquare. Such is the compoſition of powers.

Again, the ſquare root of 16 is 4, becauſe 4 is the quotient of 16 divided by 4; and the cube root of 64 is likewiſe 4, as 4 is the quotient of 64 divided by the ſquare of 4. Such is the extraction of roots.

Hence to extract the root out of a given power, is the ſame thing as to find a number, *e.gr.* 4, which being multiplied a certain number of times into itſelf, produces the given power, *e.gr.* 16 or 64.

For the extraction of ſquare and cube roots, it is neceſſary to have the ſquares and cubes of all the digits in readineſs; as exhibited in the following table.

Roots	1	2	3	4	5	6	7	8	9
Square	1	4	9	16	25	36	49	64	81
Cube	1	8	27	64	125	216	343	512	729

To extract the ſquare root out of a given number.—1. Divide the given number into claſſes, of two figures a-piece; and include each claſs between two dots, commencing with the place of units, and proceeding to the left in integers, and to the right in decimals; the root will conſiſt of ſo many parts or figures as you have claſſes. By the way obſerve, it may happen, that for the laſt claſs on the left hand there ſhall be only one figure left.

2. Then the left-hand claſs being the ſquare of the firſt figure of the root ſought, look in the table of roots for the ſquare root anſwering to that number; or, if that ſquare number be not preciſely there, to the next leſſer number: this root write down for the firſt figure of the quotient; and ſubtract its ſquare from the left-hand claſs. To the remainder bring down the next claſs toward the right.

3. Write down the double of the quotient figure under the left-hand figure of the ſecond claſs; and ſeek how oft this duple is contained in the figure over it: the quotient gives the ſecond figure of the root.

4. Write the ſame quotient under the right-hand figure of the ſame claſs, and ſubtract the product of the whole number underwritten, multiplied by the ſecond figure of the root, from the number over it, as in diviſion.

5. The operation being repeated according to the third and fourth ſteps, *i. e.* the remainder being ſtill divided by the double of the root as far as extracted; and from the remainder ſubtract the product of the laſt diviſor, having the laſt found figure of the quotient added to it, multiplied by this figure, you will have the root required.

E. gr. To extract the root of 99856, point it after the following manner, $\dot{9}9\dot{8}5\dot{6}$: then ſeek a number, whoſe ſquare ſhall equal the firſt figure 9, *viz.* 3, and write it in the quotient; then having ſubtracted from 9, 3 × 3, or 9, there will remain 0; to which ſet down the figures as far as the next point, *viz.* 98, for the following operation. Then, taking no notice of the laſt figure 8, ſay, How many times is the double of 3, or 6, contained in the firſt figure 9? Anſwer, 1. Wherefore, having written 1 in the quotient, ſubtract the product, of 1 × 61, or 61 from 98, and there will remain 37, to which connect the laſt figures 56, and you will have the number 3756, in which the work is next to be carried on. Wherefore, alſo neglecting the laſt figure of this, *viz.* 6, ſay, How many times is the double of 31, or 62, contained in 375 (which may be gueſſed at from the initial figure 6 and 37, by taking notice how many times 6 is contained in 37)? Anſwer 6; and writing 6 in the quotient, ſubtract 6 × 626, or 3756, and there will remain 0; whence it appears, that the buſineſs is done, the root coming out 316.

       ----------
```

Firſt having pointed it, ſeek a number, whoſe ſquare (if it cannot be exactly equalled) ſhall be the next leſs ſquare (or neareſt) to 22, the figures to the firſt point, and you will find it to be 4. For 5 × 5, or 25, is greater than 22; and 4 × 4, or 16, is leſs; wherefore 4 will be the firſt figure of the root. This, therefore, being writ in the quotient, from 22 take the ſquare 4 × 4, or 16; and to the remainder 6, adjoin the next figures 17, and you will have 617; from whoſe diviſion, by the double of 4, you are to obtain the ſecond figure of the root, *viz.* neglecting the laſt figure 7, ſay, how many times is 8 contained in 61? Anſwer, 7; wherefore write 7 in the quotient, and from 617 take the product of 7 into 87, or 609, and there will remain 8, to which join the two next figures 87, and you will have 887; by the diviſion whereof by the double of 47, or 94, you are to obtain the third figure; in order to which ſay, how many times is 94 contained in 88? Anſwer, 0; wherefore write 0 in the quotient, and adjoin the two laſt figures 91, and you will have 88791, by whoſe diviſion by the double of 470, or 940, you are to obtain the laſt figure; *viz.* ſay, how many times 940 in 8879? Anſwer, 9; wherefore write 9 in the quotient, and you will have the root 4709. But ſince the product 9 × 9409, or 84681, ſubtracted from 88791, leaves 4110, the number 4709 is not the root of the number 22178791 preciſely, but a little leſs.

If then it be required to have the root approach nearer, carry on the operation in decimals, by adding to the remainder two cyphers in each operation. Thus, the remainder 4110, having two cyphers added to it, becomes 411000; the diviſion whereof, by the double of 4709, or 9418, will give the firſt decimal figure 4. Then having writ 4 in the quotient, ſubtract 4 × 94184, or 376736, from 411000, and there will remain 34264. And ſo having added two more cyphers, the work may be carried on at pleaſure, the root at length coming out 4709, 43637, &c.

But when the root is carried on half way or above, the reſt of the figures may be obtained by diviſion alone: as in this example, if you have a mind to extract the root to nine figures, after the five former 4709,4 are extracted, the four latter may be had, by dividing the remainder by the double of 4709,4.

Thus if the root of 32976 were to be extracted to five places, in numbers; after the figures are pointed, write 1 in the quotient, as being the figure of whoſe ſquare 1 × 1, or 1, is the greateſt that is contained in 3, the figure to the firſt point; and having taken the ſquare of 1 from 3, there will remain 2; then having ſet the two next figures, *viz.* 29, to it (*viz.* to 2,) ſeek how many times the double of 1, *viz.* 2, is contained in 22, and you will find indeed that it is contained more than ten times; but you are never to take your diviſor 10 times, nor even 9 times in this caſe; becauſe the product of 9 × 29, or 261, is greater than 229, from which it would be to be taken, or ſubtracted; wherefore write only 8. And then having written 8 in the quotient, and ſubtracted 8 × 28, or 224, there will remain 5; and having ſet down to this the figures 76, ſeek how many times the double of 18, or 36, is contained in 57, and you will find one, and ſo write 1 in the quotient; and having ſubtracted 1 × 361, or 361, from 576, there will remain 215. Laſtly, to obtain the remaining figures, divide this number 215, by the double of 181, *viz.* 362, and you will have the figures, 59 which, being writ in the quotient, give the root 181,59. After the ſame manner are roots extracted out of decimal numbers. Thus the root of 329,76 is 18,159; and the root of 3,2976 is 1,8159, and the root of 0,032976, is 0,18159, and ſo on. But the root of 3297,6 is 57,4247; and the root of 32,976 is 5,74247. And thus the root of 9,9856 is 3,16.

```

To extract the other, or higher root, out of a given number.—The extraction of the cubic root, and all other roots, may be comprehended under one general rule; *viz.* every third figure, beginning from unity, is firſt to be pointed, if the root to be extracted be a cubic one; or every fifth, if it be a quadrato-cubic (or of the fifth power;) and then ſuch a figure is to be writ in the quotient, whoſe greateſt power (that is, whoſe cube, if it be a cubic power, or whoſe quadrato-cube, if it be the fifth power, &c.) ſhall either be equal to the figure, or figures, before the firſt point, or next leſs under them; and then having ſubtracted that power, the next figure will be found by dividing the remainder augmented by the next figure of the reſolvend, by the next leaſt power of the quotient multiplied by the index of the power to be extracted, that is, by the triple ſquare, if the root be a cubic one; or by the quintuple biquadrate, (that is, five times the biquadrate,) if the root be of the fifth power, &c. And having again ſubtracted the power of the whole quotient from the firſt reſolvend, the third figure will be found by dividing that remainder, augmented by the next figure of the reſolvend, by the next leſſer power of the whole quotient, multiplied by the index of the power to be extracted.

Thus, to extract the cube root of 13312053, the number is firſt to be pointed after this manner, *viz.* 13312053 then you are to write the figure 2, whoſe cube is 8, in the firſt place of the quotient, as that which is the next leſſer cube to the figure 13, (which is not a perfect cube number) or as far as the firſt point; and having ſubtracted that cube, there will remain 5; which being augmented by the next figure of the reſolvend 3, and divided by the triple ſquare of the quotient 2, by ſeeking how many times 3 × 4, or 12, is contained in 53, gives 4, or the ſecond figure of the quotient. But ſince the cube of the quotient 24, *viz.* 13824, would come out too great to be ſubtracted from the figures 13312, that precede the ſecond point, there muſt only 3 be writ in the quotient; then the quotient 23 being in a ſeparate place multiplied by 23, gives the ſquare 529, which again multiplied by 23, gives the cube 12167; and this taken from 13312, will leave 1145, which augmented by the next figure of the reſolvend 0, and divided by the triple ſquare of the quotient 23, *viz.* by ſeeking how many times 3 × 529, or 1587, is contained in 11450, gives 7, for the third figure of the quotient. Then the quotient 237, multiplied by 237, gives the ſquare 56169, which again multiplied by 237, gives the cube 13312053; and this taken from the reſolvend, leaves 0. Whence it is evident, that the root ſought is 237.

```
                    13312053 (237
Sub. the cube 8

```

So alſo, to extract the quadrato-cubical root of 36430820, it muſt be pointed over every fifth figure; and the figure 3, whoſe quadrato-cube, or fifth power 243, is the next leſſer to 364, *viz.* to the firſt point, muſt be writ in the quotient. Then the quadrato-cube 243 being ſubtracted from 364, there remains 121, which augmented by the next figure of the reſolvend, *viz.* 3, and divided by five times the biquadrate of the quotient, *viz.* by ſeeking how many times 5 × 81, or 405, is contained in 1213, gives two for the ſecond figure. That quotient 32 being thrice multiplied by itſelf, makes the biquadrate 1048576; and this again, multiplied by 32, makes the quadrato-cube 33554432, which, being ſubtracted from the reſolvend, leaves 2876388. Therefore 32 is the integral part of the root but not the true root; wherefore, if you have a mind to proſecute the work in decimals, the remainder, augmented by a cypher, muſt be divided by five times the aforeſaid biquadrate of the quotient, by ſeeking how many times 5 × 1048576, or 5242880, is contained in 2876388,0, and there will come out the third figure, or the firſt decimal 5. And ſo by ſubtracting the quadrato-cube of the quotient 32,5, from the reſolvend, and dividing the remainder by five times its biquadrate, the fourth figure may be obtained. And ſo on *in infinitum.*

In ſome caſes it is convenient only to indicate the extraction of a root, eſpecially where it cannot be had exactly. Now, the ſign or character whereby roots are denoted, is $\surd$; to which is added, the exponent of the power, if it be above a ſquare, and even ſometimes if it be not. *E. gr.* $\sqrt[2]{}$ denotes the ſquare root; $\sqrt[3]{}$ the cube root, &c. See Root.

When a biquadratic root is to be extracted, you may extract twice the ſquare root, becauſe $\sqrt[4]{}$ is as much as $\surd \times \surd$. And when the cubo-cubic root is to be extracted, you may firſt extract the cube root, and then the ſquare root of that cube root, becauſe the $\sqrt[6]{}$ is the ſame as $\sqrt[2]{} \times \sqrt[3]{}$; whence ſome have called theſe roots, not cubo-cubic ones but quadrato-cubes. And the ſame is to be obſerved in other roots, whoſe indices are not prime numbers.

To prove the extraction of roots.—1. For a *ſquare root*; multiply the root found by itſelf, and to the product add the remainder, if there were any: if the ſum be equal to the number given, the operation is juſt.

2. For a *cube root.* Multiply the root found by itſelf, and the product, again, by the ſame root. To the laſt product, add the remainder, if there were any. If the ſum come out the number firſt given, the work is juſt.

After the like manner may the extraction of the other roots be proved.

To extract the roots of equations, or algebraic quantities.—The extraction of roots out of ſimple algebraic quantities, is evident, even from the nature, or marks of notation itſelf; as that $\sqrt{aa}$ is a, and that $\sqrt{aacc}$ is ac, and that $\sqrt{9aacc}$ is 3ac; and that $\sqrt{49a^4xx}$ is 7aax. And alſo that $\sqrt{\frac{a^4}{cc}}$, or $\frac{\sqrt{a^4}}{\sqrt{cc}}$ is $\frac{aa}{c}$, and that $\sqrt{\frac{a^4bb}{cc}}$ is $\frac{aab}{c}$, and that $\sqrt{\frac{9aazz}{25bb}}$ is $\frac{3az}{5b}$, and that $\sqrt{\frac{4}{9}}$ is $\frac{2}{3}$, and that $\sqrt[3]{\frac{8b^6}{27a^3}}$ is $\frac{2bb}{3a}$, and that $\sqrt[4]{aabb}$ is $\sqrt{ab}$; moreover, that $b\sqrt{aacc}$, or b into $\sqrt{aacc}$, is equivalent to b into ac, or abc: and that $3c\sqrt{\frac{9aazz}{25bb}}$ is equivalent to $3c \times \frac{3az}{5b}$, or $\frac{9acz}{5b}$. And that $\frac{a+3x}{c}\sqrt{\frac{4bbx^4}{81aa}}$ is equivalent to $\frac{a+3x}{c} \times \frac{2bxx}{9a}$, or to $\frac{2abxx+6bx^3}{9ac}$ I ſay all theſe are evident, becauſe it will appear at firſt ſight, that the propoſed quantities are produced, by multiplying the roots into themſelves (as aa from a into a; aacc from ac into ac; 9aacc from 3ac into 3ac, &c.) The rule is to extract the required root of the numeral coefficient, if there be any, and to divide the exponents of the literal or algebraic quantities by the number that denominates the root required. It is evident from the application of this rule, that any power which has a poſitive ſign may have either a poſitive or negative root, if the root is denominated by an even number, becauſe + or −, multiplied into themſelves an even number of times will give +. Alſo, that if a power have a negative ſign, no root of it denominated by an even number can be aſſigned. But if the root to be extracted is denominated by an odd number, the ſign of the root will be the ſame as the ſign of the given quantity whoſe root is required. However, it will often happen, that the number, denominating the required root, will not exactly divide the exponent of the given power, in which caſe the required root will have a fractional exponent, thus, $\sqrt[3]{8a}$ is $= 2a\frac{1}{3}$. But when quantities conſiſt of ſeveral terms, the buſineſs is performed as in numbers.

Thus, to extract the ſquare root out of aa + 2ab + bb; in the firſt place, write the root of the firſt term aa, *viz.* a, in the quotient; and having ſubtracted its ſquare a × a, there will remain 2ab + bb to find the remainder of the root by. Say, therefore, how many times is the double of the quotient, or 2a, contained in the firſt term of the remainder 2ab? I anſwer, b [times]: therefore write b in the quotient, and having ſubtracted the product of b into 2a + b, or 2ab + bb, there

```
aa + 2ab + bb (a + b
aa
—
 0 + 2ab + bb
   + 2ab + bb
 ——————————————
    0     0
```

there will remain nothing; which ſhews that the work is finiſhed, the root coming out $a + b$.

And thus to extract the ſquare root out of $a^4 + 6a^3b + 5aabb - 12ab^3 + 4b^4$, firſt ſet in the quotient the root of the firſt term a^4, *viz.* aa, and having ſubtracted its ſquare $aa \times aa$, or a^4, there will remain $6a^3b + 5aabb - 12ab^3 + 4b^4$ to find the remainder of the root. Say, therefore, how many times is $2aa$ contained in $6a^3b$? Anſwer, $3ab$; wherefore write $3ab$ in the quotient; and having ſubtracted the product of $3ab$, into $2aa + 3ab$, or $6a^3b + 9aabb$, there will yet remain $-4aabb - 12ab^3 + 4b^4$, to carry on the work. Therefore, ſay again, how many times is the double of the quotient, *viz.* $2aa + 6ab$, contained in $-4aabb - 12ab^3$? or, which is the ſame thing, ſay, how many times is the double of the firſt term of the quotient, or $2aa$, contained in the firſt term of the remainder $-4aabb$? Anſwer, $-2bb$. Therefore having writ $-2bb$ in the quotient, and ſubtracted the product $-2bb$ into $2aa + 6ab - 2bb$, or $-4aabb - 12ab^3 + 4b^4$, there will remain nothing.

Whence it follows, that the root is $aa + 3ab - 2bb$.

$$\begin{array}{l}
a^4 + 6a^3b + 5aabb - 12ab^3 + 4b^4 \;(aa + 3ab - 2bb \\
a^4 \\
\overline{\quad} 6a^3b + 5aabb - 12ab^3 + 4b^4 \\
0 + 6a^3b + 9aabb \\
\hline
\quad 0 - 4aabb - 12ab^3 + 4b^4 \\
\quad\;\; - 4aabb - 12ab^3 + 4b^4 \\
\hline
\qquad\quad 0 \qquad\quad 0 \qquad\quad 0
\end{array}$$

And thus the ſquare root of the quantity $xx - ax + \frac{1}{4}aa$ is $x - \frac{1}{2}a$, and the ſquare root of the quantity $16a^4 - 24aaxx + 9x^4 + 12bbxx - 16aabb + 4b^4$ is $3xx - 4aa + 2bb$, and the ſquare root of the quantity $y^4 + 4y^3 + 8y^2 + 8y + 4$ is $yy + 2y + 2$; as may appear underneath.

1.
$$\begin{array}{l}
xx - ax + \frac{1}{4}aa \;(x - \frac{1}{2}a \\
xx \\
\hline
0 - ax + \frac{1}{4}aa \\
\hline
\qquad 0 \quad 0
\end{array}$$

2.
$$\begin{array}{l}
9x^4 \begin{array}{l} -24aa \\ +12bb \end{array} x^2 \begin{array}{l} +16a^4 \\ -16aabb \\ +4b^4 \end{array} \quad \left(3x^2 \begin{array}{l} -4aa \\ +2bb \end{array}\right. \\
9x^4 \\
\hline
0 \quad \begin{array}{l} -24aa \\ +12bb \end{array} x^2 \begin{array}{l} +16a^4 \\ -16a^2b^2 \\ +4b^4 \end{array} \\
\hline
\quad 0 \qquad 0
\end{array}$$

3
$$\begin{array}{l}
y^4 + 4y^3 + 8y^2 + 8y + 4 \;(yy + 2y + 2 \\
y^4 \\
\hline
0 \\
4y^3 + 8yy \\
\hline
\quad 0 + 4yy + 8y + 4 \\
\quad\;\; + 4yy + 8y + 4 \\
\hline
\qquad\quad 0 \qquad 0 \qquad 0
\end{array}$$

If you would extract the cube root out of $a^3 + 3aab + 3abb + b^3$, the operation is performed thus:

$$\begin{array}{l}
\quad a^3 + 3aab + 3abb + b^3 \;(a + b \\
\quad a^3 \\
3aa)\; 0 + 3aab \;(b \\
\hline
\quad a^3 + 3aab + 3abb + b^3 \\
\hline
\qquad\quad 0 \qquad\quad 0 \qquad\quad 0
\end{array}$$

Extract firſt the cube root of the firſt term a^3, *viz.* a, and ſet it down in the quotient: then ſubtracting its cube a^3; ſay, how many times is its treble ſquare, or $3aa$, contained in the next term of the remainder $3aab$; and there comes out b; wherefore write b in the quotient, and ſubtracting the cube of the quotient $a+b$, there will remain 0; therefore $a + b$ is the root. After the ſame manner, if the cube root is to be extracted out of $z^6 + 6z^5 - 40z^3 + 96z - 64$, it will come out $zz + 2z - 4$. And ſo likewiſe in higher roots.

The general rule for extracting any root out of any given quantity, is as follows. Having ranged the quantity according to the dimenſions of its letters, extract the ſaid root out of the firſt term, and that ſhall be the firſt member of the root required; then raiſe this root to a dimenſion lower by unit than the number that denominates the root required; and multiply the power that ariſes by that number itſelf; divide the ſecond term of the given quantity by the product, and the quotient ſhall give the ſecond member of the root required. The other members of the root, if there be more than two, are found after the ſame manner. In ſome caſes the exact root cannot be found in finite terms: thus, the ſquare root of $a^2 + x^2$ is found to be $a + \frac{x^2}{2a} - \frac{x^4}{8a^3} + \frac{x^6}{16a^5} - \frac{5x^8}{128a^7}$, &c.

The operation is thus:

$$\begin{array}{l}
\qquad\qquad a^2 + x^2 \;\left(a + \frac{x^2}{2a} - \frac{x^4}{8a^3} + \frac{x^6}{16a^5}\right., \text{&c.} \\
\qquad\qquad a^2 \\
2a + \left.\frac{x^2}{2a}\right) * + x^2 \\
\quad \times \left.\frac{x^2}{2a}\right) = x^2 + \frac{x^4}{4a^2} \\
\hline
2a + \frac{x^2}{a} - \left.\frac{x^4}{8a^3}\right) - \frac{x^4}{4a^2} \\
\quad \times -\left.\frac{x^4}{8a^3}\right) = -\frac{x^4}{4a^2} - \frac{x^6}{8a^4} + \frac{x^8}{64a^6} \\
\hline
\qquad\qquad + \frac{x^6}{8a^4} - \frac{x^8}{64a^6}, \text{&c.}
\end{array}$$

In the ſame manner the cube root of $a^3 + x^3$ will be found to be $a + \frac{x^3}{3a^2} - \frac{x^6}{9a^5} + \frac{5x^9}{81a^7} - \frac{10x^{12}}{243a^{11}}$, &c. Thus,

$$\begin{array}{l}
\quad a^3 + x^3 \left(a + \frac{x^3}{3a^2}\right. \\
\quad a^3 \\
3a^2)\; * x^3.
\end{array}$$

Then cube $a + \frac{x^3}{3a^2}$, and we ſhall have $a^3 + x^3 + \frac{x^6}{3a^3} + \frac{x^9}{27a^3}$, which ſubtracted from the given quantity $a^3 + x^3$, leaves $-\frac{x^6}{3a^3} - \frac{x^9}{27a}$ for the next reſolvend; and this divided by $3a^2$ will give $-\frac{x^6}{9a^5}$ for the next term of the quotient, &c. But the roots of quantities of this kind are much more expeditiouſly obtained by means of the binomial theorem. For the ſquare root of $a^2 + x^2 = \overline{a^2+x^2}^{\frac{1}{2}}$; and $\overline{a^2+x^2}^{\frac{1}{2}} = \overline{a^2}^{\frac{1}{2}} + \frac{1}{2} \times \overline{a^2}^{\frac{1}{2}-1} \times x^2 + \frac{1}{2} \times \frac{\frac{1}{2}-1}{2} \times \overline{a^2}^{\frac{1}{2}-2} \times \overline{x^2}^2 + \frac{1}{2} \times \frac{\frac{1}{2}-1}{2} \times \frac{\frac{1}{2}-2}{3} \times \overline{a^2}^{\frac{1}{2}-3} \times \overline{x^2}^3$, &c. $= \overline{a^2}^{\frac{1}{2}} + \frac{1}{2} \times \overline{a^2}^{-\frac{1}{2}} x^2 + \frac{1}{2} \times -\frac{1}{4} \times \overline{a^2}^{-\frac{3}{2}} x^4 + \frac{1}{2} \times -\frac{1}{4} \times -\frac{1}{2} \times \overline{a^2}^{-\frac{5}{2}} x^6$, &c. $= a + \frac{1}{2} \times a^{-1} x^2 - \frac{1}{8} \times a^{-3} x^4 + \frac{1}{16} \times a^{-5} x^6$, &c. = (bringing the powers of a from the numerators to the denominators, by changing the ſigns of their exponents) $a + \frac{x^2}{2a} - \frac{x^4}{8a^3} + \frac{x^6}{16a^3}$, &c.

Thus alſo the cube root of $a^3 + x^3 = \overline{a^3+x^3}^{\frac{1}{3}}$; and $\overline{a^3+x^3}^{\frac{1}{3}} = \overline{a^3}^{\frac{1}{3}} + \frac{1}{3} \times \overline{a^3}^{\frac{1}{3}-1} \times x^3 + \frac{1}{3} \times \frac{\frac{1}{3}-1}{2} \times \overline{a^3}^{\frac{1}{3}-2} \times \overline{x^3}^2 + \frac{1}{3} \times \frac{\frac{1}{3}-1}{2} \times \frac{\frac{1}{3}-2}{3} \times \overline{a^3}^{\frac{1}{3}-3} \times \overline{x^3}^3$, &c. $= \overline{a^3}^{\frac{1}{3}} + \frac{1}{3} \times \overline{a^3}^{-\frac{2}{3}} x^3 + \frac{1}{3} \times -\frac{1}{3} \times \overline{a^3}^{-\frac{5}{3}} x^6 + \frac{1}{3} \times -\frac{1}{3} \times -\frac{5}{9} \times \overline{a^3}^{-\frac{8}{3}} x^9$, &c. $= a + \frac{1}{3} \times a^{-2} x^3 - \frac{1}{9} \times a^5 \times x^6 + \frac{5}{81} a^{-8} x^9$, &c. $= a + \frac{x^3}{3a^2} - \frac{x^6}{9a^5} + \frac{5x^9}{81a^8}$, &c. See Maclaurin's Algebra, part i. ch. viii. p. 50, 51. See ROOT.

EXTRACTOR, in *Midwifery*, an inſtrument contrived to extract children in caſes of difficult births. We have the deſcription of a forceps for extracting children by the head when lodged low in the pelvis of the mother, in the Medic. Eſſ. Edinb. vol. iii. art. 20. See alſo the abridgment of this book, vol. ii. p. 438, where ſome alteration is mentioned of this inſtrument from Giffard's Midwifery, and an improvement of it by Mr. Freke. See FORCEPS.

EXTRACTUM CATHARTICUM, a form of medicine in the London Diſpenſatory, intended as an equivalent for the *extractum Rudii*, commonly called Rudius's pill, and which is for many reaſons a better compoſition than that pill. It is now called "extractum colocynthidis compoſitum." See COLOCYNTHIS.

EXTRADOS, the outſide of a vault.

EXTRANEOUS FOSSILS, in *Geology*. Adventitious, ſecondary, or figured foſſils, have among them (ſee FOSSILS, *Extraneous*) thoſe remains and exuvia of organized beings, which are found imbedded in the ſtrata of the earth. Since the diſcovery of Mr. William Smith, that each particular ſhell, and other organic remain, has its proper and appropriate place in the lamina of ſome particular ſtratum, and of which it is often a perfect, and, perhaps, the moſt unerring teſt of identity, in moſt inſtances, the knowledge and exact diſcrimination of theſe numerous animal and vegetable remains has appeared a matter of the firſt importance to geologiſts, eſpecially ſince it has been further aſcertained, as it now is, that moſt, if not every one, of the organic remains, differ eſſentially from any recent ſpecies of the animals and plants, to which former, and too curſory, obſervations had referred them; while many of them differ altogether and entirely from any thing now living or growing: which two points aſcertained, have tended irreſiſtibly to ſhew that theſe organic remains were not entombed by the Moſaic deluge, as moſt writers had ſuppoſed, becauſe they differ entirely from the antediluvian race, of which the preſent living ones are the deſcendants and exact repreſentatives, as the Moſaic account informs us, and are not of ſubſequent creation. Another reſult of the former of theſe facts has been to ſhew, that the ſeveral animals and plants whoſe foſſil remains we meet with in the ſtrata, lived and died on the ſtratum in which we find them, prior to the depoſition, and, perhaps, prior alſo to the creation of the matter of the lamina which covers them; and that the period of the exiſtence of particular ſpecies was in moſt, if not every inſtance, limited to that took up in the depoſition of the particular ſtratum in which they are found imbedded, ſeeming to ſuggeſt, that they were *created* at the period of the ſtratification, which anſwers to the loweſt lamina in which they are found, and ceaſed to exiſt altogether at the period anſwering to the higheſt lamina in which they are found; a ſuppoſition in no ways inconſiſtent with the Moſaic account of creation, if the whole of the foſſil race be different from the preſent race of organized beings, and of a period of time antecedent to the events deſcribed by the ſacred hiſtorian, except in his introductory words, "In the beginning God created the heavens and the earth." It may, poſſibly, be urged, againſt the idea of a temporary duration of the primitive animals and plants, and their becoming after that *extinct*, that the ſame kind of organic remains are found again, after large ſucceſſions of depoſitions with remains of different beings, in aſcending the ſeries of ſtrata, or in very diſtant parts of the globe; to which it may be anſwered, that where ſufficient diſcrimination has been made in the ſpecific differences of organic remains reſembling each other, but found imbedded in a ſtrata ſeparated by thoſe of a different kind, and with different kinds of organic beings in them, it has generally, if not always, turned out, that the remains reſembling each other, and hitherto ſuppoſed identic, are in reality not ſo, but of perfectly diſtinct ſpecies; their *varieties*, as ſome might be diſpoſed to call them, in conformity to the language of the naturaliſts reſpecting accidental deviations in ſome recent ſpecies, being *conſtant*, and ſuch as properly conſtituted diſtinct ſpecies in the great families of the primitive creation. Reſpecting organic ſubſtances found at very diſtant places on the globe, which, on being brought together and thoroughly examined, appear to be identic; before any argument is drawn therefrom, againſt the temporary exiſtence and extinction of their originals in the primitive race which inhabited the waters of this globe, it ſhould be diſtinctly aſcertained that the ſeries of ſtrata and organic remains above and below the two places in the ſeries whence the ſpecimens were brought are really different; or, in other words, that the identic ſpecies really do belong to different parts of the ſeries of ſtrata: for if, on the contrary, they belong to the *ſame ſtratum*, however its obvious mineralogical character may appear changed, it is to be expected that the organic remains will be identic, ſince Mr. Smith has, on tracing the ending or actual out-crop of a ſtratum for ſeveral hundred miles, always found the organic remains the ſame; as the numerous ſpecimens in his collection, marked and brought from the extreme and intermediate points of ſuch examination, do teſtify.

It is alſo to be taken into conſideration, that the diſcoveries of Mr. Farey, relative to denudated tracts on our globe, ſhew the poſſibility, and, perhaps, the frequent occurrence of ſuch deep excavations being left in the ſtrata of the earth, as to exhibit the edges, and indeed conſiderable tracts of the planes of ſtrata, at immenſe depths in the ſeries, below thoſe proper to the general ſtrata on the ſurface, and having their regular baſſet, or ending, on the ſurface, at great diſtances from ſuch denudated expoſures of them. The immenſe denudation, for inſtance, which has laid bare the fourth or loweſt limeſtone rock of Derbyſhire and Staffordſhire, and the excavation of Dove-dale and other vallies therein, appears to have expoſed ſtrata to view, which are from 1½ to 2 miles in perpendicular depth beneath the red earth, or gypſeous tract, which ſurrounds them on all ſides! (except, perhaps, a narrow ſtrip on the north, along the grand ridge, or waterſhead of the iſland,) which lower expoſed parts of the fourth lime rock do not, perhaps, anywhere baſſet, or come regularly to the ſurface, within 90 or 100 miles of Dove-dale and other vallies, where the denudation has expoſed them. The continents ſeem, from the relations of travellers, likely to furniſh numerous inſtances of denudations in the mountain chains, which will be found to expoſe ſtrata that lie very low indeed in the general ſeries, and at very great diſtances from the regular or continued line of ending or outcrop of thoſe particular ſtrata; and, without adverting to which circumſtances, the exact identity of organic remains from diſtant places ſo circumſtanced, might ſeem to contradict our ideas of their being peculiar to peculiar ſtrata. But after all, ſhould identically the ſame ſpecies of organic remains be found in diſtant parts of the ſeries of terreſtrial ſtrata, what have we to limit the architect of "heaven and earth," from having re-created ſimilar animals or plants during the countleſs periods of the primitive creation and exiſtence? Analogy ſurely cannot be ſaid to do this, when the animals and plants created ſince he ſaid "Let the waters be gathered together, and let the *dry land* appear," and which ſtill continue to exiſt, have ſo many points of reſemblance to ſome of the primitive and extinct ones, both in forms and habits, that they have for ages paſſed as identic therewith. Mr. James Parkinſon and Mr. W. Martin, having engaged in works intended to collect information on, and more accurately to diſcriminate, extraneous or organic foſſil remains, which works are ſtill in progreſs, and the reſults of Mr. W. Smith's labours and thoſe of his pupils being yet in a great meaſure unpubliſhed, we ſhall defer what we have further to add on theſe highly intereſting and curious relics to the article RELIQUIA, which ſeems, indeed, their more appropriate title. In the mean time, as the uſual names of the ſeveral foſſil animals and plants, &c. occur, we ſhall not fail to lay before our readers ſuch facts and particulars as we can collect, and with propriety communicate, concerning the objects of the unpubliſhed reſearches of the meritorious individuals alluded to; to whoſe credit it ought to be known, that extended and undiſguiſed communications have all along been made among the circle of their friends, and in conſequence of which a ſpirit of enquiry on the ſubject has been excited, in various diſtricts of the kingdom, from which the happieſt conſequences to ſcience may be expected ſhortly to ariſe.

EXTRANEONS, *Extraneus*, Lat. belonging to nothing, forcing. This word, during the laſt century, was admitted into the muſical technica, in ſpeaking of an unuſual and irregular change of key, which is called extraneous modulation, or modulating into an unrelative key, as in the key of C natural, D with a ſharp 3d, D♭, B♮, and B♭, which are unrelative keys, having no ſound in common with the chord of C natural. With reſpect to extraneous modulation, Rouſſeau ſays that no compoſers have frequent recourſe to ſudden and unuſual modulation, but thoſe who are ſteril in fancy and invention: and we ſhould believe the aſſertion well founded, if Eman. Bach, Haydn, and Mozart, were excepted, who cannot be accuſed of want of invention. It is to the clumſy imitators of theſe great maſters, who, in total want of melody, have recourſe to unexpected harmony, that Rouſſeau's accuſation ſeems to attach.

EXTRAORDINARII, in *Roman Antiquity*, a body of forces, conſiſting of a third part of the horſe, and a fifth part of the foot, which was ſeparated from the reſt, to prevent any deſign that might be formed againſt the natural forces. See ABLECTI.

EXTRAORDINARY, ſomething out of the common courſe.

EXTRAORDINARY *couriers*, are thoſe ſent expreſs on ſome urgent occaſion.

EXTRAORDINARY *embaſſador*, or *envoy*, is ſuch a one as is ſent to treat or negociate ſome ſpecial and important affair, as a marriage, a treaty, confederacy, &c. or even on occaſion of ſome ceremony, as condolence, congratulation, &c. See EMBASSADOR.

A gazette, journal, or other news-paper extraordinary, is that publiſhed after ſome great and notable event, containing the detail or particulars thereof, which are not found in the ordinary papers. Our news-writers generally uſe poſtſcripts, or ſupplements, inſtead of extraordinaries.

EXTRAORDINARY *culverin*. See CULVERIN.

EXTRAVAGANTES, a part of the canon law, containing divers conſtitutions of the popes, not included in the body of the canon-law; whence the denomination extravagantes: "quaſi extra corpus juris vagantes."

The extravagantes are divided into two parts: the firſt contains twenty conſtitutions of John XXII. and the ſecond other later conſtitutions of the ſaid John, and his ſucceſſors. See CANON-*Law*, and DECRETALS.

EXTRAVASATION, a term in *Surgery*, derived from *extra*, *out of*, and *vaſa*, *the veſſels*; it ſignifies an effuſion of any fluid from the veſſels, viſcus, or receptacle, in which ſuch fluid is naturally contained, and the paſſage of the ſame into another ſituation, which is very frequently the interſtices of the cellular membrane. In the head, blood is often extravaſated, under the cranium, upon the ſurface of the dura mater, in conſequence of the rupture of one of the arteries of this membrane from external violence. The ſame fluid is alſo frequently extravaſated on the pia mater, and in the convolutions of the cerebrum, or, more deeply in the ventricles, and very ſubſtance of the brain.

In caſes of wounds of the abdomen, large quantities of blood are occaſionally extravaſated in the cavity of the peritonæum, or the contents of the ſtomach, bowels, gall-bladder, or ſome other injured viſcus, may become effuſed. When the urinary bladder is wounded, or when a ſlough takes place in a certain part of it, from the diſtenſion occaſioned by a long protracted, and unrelieved retention of urine, the latter fluid may become extravaſated in the abdomen. In the example of ſtrictures, the urethra occaſionally ulcerates between the obſtruction, and the neck of the bladder, and the urine is conſequently extravaſated in the cellular membrane of the perinæum and ſcrotum. Sometimes, when a portion of the bowels mortifies, after being returned into the belly, in caſes of hernia, the inteſtinal matter eſcapes from the alimentary canal, through the breach occaſioned by the ſloughing.

In the thorax, ſurgeons ſometimes have opportunities of ſeeing caſes, in which conſiderable extravaſations of blood ariſe, in conſequence of ſtabs and gun-ſhot wounds.

In the limbs, and indeed, we might ſay, in every ſituation, practitioners frequently meet with extravaſations of blood, in caſes of wounded arteries, aneuriſms, and violent contuſions and blows, which rupture veſſels of important ſize. Bloody ſwellings, produced in the laſt-mentioned manner, are technically named ecchymoſes, and have already been treated of elſewhere. See Ecchymosis.

Our deſign, in the preſent place, is to conſider extravaſations in a ſurgical point of view, as they occur in the head, the cheſt, and the belly; taking occaſion, however, to refer the reader for certain parts of the ſubject to other places in this work.

Extravaſation of blood in the head, from external violence.—After explaining with equal perſpicuity and elegance, how the dura mater ſerves as a perioſteum to the internal ſurface of the bones of the cranium, in the ſame manner as the pericranium does to the external table, Mr. Pott notices, that by blows, falls, and other ſhocks, ſome of the larger of the veſſels, which carry on the communication between the dura mater and the ſkull, may be broken, and a quantity of blood ſhed upon the ſurface of that membrane. This, he obſerves, is one ſpecies of bloody extravaſation, and, indeed, the only one which can be formed between the ſkull and dura mater. If the broken veſſels be few, and the quantity of blood which is ſhed, be ſmall, the ſymptoms are generally ſlight, and, by proper treatment, diſappear: when they are large, or numerous, or the quantity of extravaſated fluid conſiderable, the ſymptoms are generally urgent in proportion; but, continues Mr. Pott, whether they be ſlight, or conſiderable, whether immediately alarming, or not, they are always, and uniformly, ſuch as indicate preſſure made on the brain and nerves, *viz.* ſtupidity, drowſineſs, diminution, or loſs of ſenſe, ſpeech, and voluntary motion.

The ſhock which the head ſometimes receives by falls from on high, or by ſtrokes from ponderous bodies, may likewiſe occaſion a breach in ſome of the veſſels, either of the pia mater, or brain, and thus produce an extravaſation of the fluid which ſhould circulate through them.

Mr. Pott remarks, that an extravaſation may be the only complaint cauſed by the accident; or it may be joined with, or added to, a fracture of the ſkull. But, this is not all; for it may be produced not only when the cranium is unhurt by the blow, but, even when no violence of any kind has been offered to, or received by the head.

Vertigo, vomiting, ſtupidity, hemorrhage, loſs of ſenſe and motion, either partial or total, are ſet down by this celebrated ſurgical author as the ſymptoms of an extravaſation within the cranium; ſometimes one or more occur in the ſame ſubject; ſometimes all of them. Theſe ſymptoms, which are all eaſily accountable for from extravaſation of fluid, and unnatural preſſure made on the brain and nerves, are, ſays Pott, frequently miſtaken as indications of a diſeaſe, which, conſidered abſtractedly, can never cauſe them; he means a ſimple undepreſſed fracture of the cranium, which may be accompanied by them, but cannot cauſe them.

The ſame writer repeats, that when a fluid is extravaſated in any conſiderable quantity within the cavity of the cranium, if any bad ſymptoms are produced by it at all, they are, and muſt be, ſuch as indicate preſſure made on the brain, and origin of the nerves, occaſioning thereby either diſturbance, or abolition of the offices of ſenſe and motion; and this in a different degree, according to the quantity, kind, and ſituation of the preſſing fluid.

Mr. Pott ſeems to have entertained the common notion of hemorrhage from the ears and noſe being alſo ſymptoms of an extravaſation. However, the leaſt reflection muſt ſoon make any body perceive, that a bleeding from thoſe parts is only indicative of their having ſuſtained a violent ſhock in common with the reſt of the head. Even the degree of violence is not at all denoted with any certainty by theſe circumſtances; for, with reſpect to the noſe, we know, that, in many perſons, the ſlighteſt cauſe will make it bleed.

When the above-mentioned ſymptoms exiſt, Mr. Pott was of opinion, that we might pronounce, in a poſitive manner, our judgment, that the brain ſuffers compreſſion; but, ſays he, to our very frequent mortification, we find theſe are the only circumſtances which, in ſuch caſe, we can depend upon; every thing elſe which relates, or belongs to them, being involved in a moſt perplexing obſcurity. We not only have no certain infallible rule whereby to diſtinguiſh what the preſſing fluid is, or where it is ſituated; but we are, in many inſtances, abſolutely incapable of knowing whether the ſymptoms be occaſioned by any fluid at all; for, a fragment of bone broken off from the internal table of the cranium, and making an equal degree of preſſure, will produce exactly the ſame complaints.

When a caſe, attended with the preceding ſymptoms, occurred, the old ſurgeons uſed in general to conclude, that the brain had ſuffered a concuſſion, to which all the conſequences were imputed.

Mr. Pott obſerves, that a concuſſion and an extravaſation are very diſtinct cauſes of miſchief, though not always very diſtinguiſhable. M. Le Dran, and others of the modern French writers, have made a very ſenſible and juſt diſtinction between that kind and degree of loſs of ſenſe, which ariſes from a mere commotion of the brain, and that which is cauſed by a mere extravaſation, in thoſe inſtances, in which the time of the attack or appearance of ſuch ſymptoms, is different, or diſtinct. The loſs of ſenſe, which immediately follows the violence, ſay they, is moſt probably owing to a commotion; but, that which comes on after an interval of time is paſt, is moſt probably cauſed by extravaſation.

Mr. Pott remarks, that this diſtinction is certainly juſt and good, as far as it will go. That degree of abolition, or diminution of ſenſe, which immediately attends, or follows the blow or fall, and goes off again, without the aſſiſtance of art, is in all probability occaſioned by the ſudden ſhake or temporary derangement of the contents of the head; and the ſame kind of ſymptoms recurring again ſome time after they had ceaſed, or not coming on until ſome time has paſſed from the receipt of the violence, do moſt probably proceed from the breach of a veſſel within, or upon the brain. But, unluckily, we have it not very often in our power to make this exact diſtinction. An extravaſation is often made ſo immediately, and ſo largely, at the inſtant of the accident, that all ſenſe and motion are inſtantaneouſly loſt, and never again return. And it alſo ſometimes happens (continues Mr. Pott), that, although an extravaſation may poſſibly not have been made at the moment of the accident, and the firſt complaints may have been owing to commotion merely, yet a quantity of fluid having been ſhed from its proper veſſels very ſoon after the accident, and producing its proper ſymptoms, before thoſe cauſed by the commotion have had time to go off, the ſimilarity of the effects of each of theſe different cauſes is ſuch, as to deprive us of all power of diſtinguiſhing between the one and the other, or of determining, with any tolerable preciſion, to which of them ſuch ſymptoms as remain are really owing.

Mr. Pott next obſerves, that the nature and degree of the ſymptoms, produced by the preſſure of an extravaſation, are various and different in different perſons, according to the kind, quantity, and ſituation of the preſſing fluid. Sometimes it is mere fluid blood; ſometimes blood in a ſtate of coagulation ; ſometimes it is a clear lymph ; and, at others, blood and water are found mixed together ; each of theſe is found either ſimple or mixed in different ſituations ; that is, between the ſkull and dura mater, between the dura and pia mater, or in the natural cavities of the brain, called its ventricles, and ſometimes, in caſes of great violence, they are found at the ſame time in all theſe different parts. Sometimes; a conſiderable quantity is ſhed inſtantly at the time of the accident ; and ſometimes the breach, by which the effuſion is made, is ſo circumſtanced, both as to nature and ſituation, that it is at firſt very ſmall, and increaſes by faſter or ſlower degrees. In the former (ſays Pott), the ſymptoms are generally immediate and urgent, and the extravaſation is of the bloody kind. In the latter, they are frequently ſlight at firſt, appear after ſome little interval of time, increaſe gradually, till they become urgent, or fatal, and are, in ſuch caſe, generally occaſioned by extravaſated lymph. So that although the immediate appearance of bad ſymptoms does moſt certainly imply miſchief of ſome kind or other, yet, on the other hand, no man ought to ſuppoſe his patient free from hazard, either becauſe ſuch ſymptoms do not ſhew themſelves at firſt, or becauſe they appear to be but ſlight ; thoſe which come on late, or, appearing ſlight at firſt, increaſe gradually, being full as much to be dreaded as to conſequence as the more immediately alarming ones ; with this material difference between them, that the one *may* be the conſequence of a mere concuſſion of the brain, and may by means of quietude and evacuation go quite off ; whereas, the other being moſt frequently owing to an extravaſation of lymph, (though ſometimes of blood alſo,) within the ſubſtance of the brain, are very ſeldom removed by art. (Pott's Works, vol. i.) It appears from ſome excellent obſervations publiſhed by Mr. Abernethy on the ſubject of injuries of the head, that a fracture of the ſkull is not likely to be followed by an equal degree of extravaſation in every part, as the veſſels, connecting the dura mater to the cranium, are in moſt parts of that membrane of a ſmall ſize. If theſe are accidentally ruptured, a ſlight hemorrhage enſues, which ſoon ſtops, and only a thin ſtratum of coagulated blood is found, if the bone be removed. But, ſays Mr. Abernethy, if the fracture happens in the track of the principal artery of the dura mater ; if the trunk, or even a conſiderable branch of that veſſel be torn, the hemorrhage will be profuſe, and the operation of the trephine becomes immediately neceſſary to preſerve the life of the patient.

When an interval of ſenſe occurs between the blow and the ſtupor occaſioned by the effuſed blood, the diſcrimination of the nature of the caſe is greatly facilitated by that circumſtance, as we have already related, becauſe it becomes manifeſt, that the bad ſymptoms, which now come on, are not owing to the firſt mere ſhock of the external violence on the brain. The patient was moſt probably ſtunned by the blow, at the very inſtant of its occurrence ; but he gradually regained his ſenſes, in proportion as the firſt effects of the ſhock on the brain ſubſided. However, as ſome veſſel was wounded by the ſame blow, an hemorrhage continues under the cranium, on, or within, the brain, and as ſoon as a certain quantity of blood is extravaſated, its preſſure produces a recurrence of ſtupefaction.

Unfortunately, great obſcurity attends numerous caſes, in conſequence of patients having no interval of ſenſe, and remaining in a ſtate of complete ſtupefaction ever after the accident. We know not, whether the brain is labouring under concuſſion, or compreſſion, or both ; and even when we do know that the bad ſymptoms ariſe from an extravaſation, we are frequently unable to ſay where the effuſed blood is ſituated. Now, ſince the operation of trepanning is not likely to afford aſſiſtance, unleſs the blood be upon the dura mater, ſo as to allow of being taken away, and ſince the operation itſelf is by no means free from danger, we ſhould be very reluctant to put it in practice without having good foundation for believing that there will be found immediately under the perforation, which we are about to make in the bone, the extravaſated blood, which gives riſe to the urgent complaints. Practitioners are highly indebted to Mr. Abernethy for a ſuggeſtion, which promiſes to be of exceedingly great aſſiſtance in directing whether the trephine ought to be uſed, or not, on a particular part of the head. "Unleſs one of the large arteries of the dura mater be wounded, (ſays this gentleman,) the quantity of blood poured out will be inconſiderable ; and the ſlight compreſſion of the brain, which this occaſions, may not be attended with any peculiar ſymptoms ; or, perhaps, it may occaſion ſome ſtupor, or excite an irritation diſpoſing the ſubjacent parts to become inflamed ; but both theſe effects will gradually abate, nor will any inflammation enſue, if proper means are taken to prevent it. It is indeed highly probable that in many caſes, which have done well without an operation, ſuch an extravaſation has exiſted. But, if there be ſo much blood on the dura mater as materially to derange the functions of the brain, the bone, to a certain extent, will no longer receive blood from within ; and by the operation performed for its expoſure, the pericranium muſt have been ſeparated from its outſide. I believe, that a bone ſo circumſtanced will not be found to bleed ; and I am certain it cannot with the ſame freedom and celerity, as it does when the dura mater remains connected with it internally."

In ſome caſes, related by Mr. Abernethy, there was not the leaſt hemorrhage, and this gentleman mentions his having twice been able, by attending to the want of hemorrhage from the outſide of the cranium, to aſcertain the extent to which the dura mater was detached within. Alſo, when ſymptoms ſeemed to require the perforation of the ſkull, Mr. Abernethy has frequently ſeen the operation contra-indicated by the hemorrhage from the bone, and rightly, as the event proved.

When the bone has been for ſome time bare, this criterion may not be ſo clear ; but Mr. Abernethy ſcraped the ſurface of a portion of the ſkull, which had remained ſome time in a denuded ſtate, and he found that it bled freely enough to denote that the dura mater was adherent to the inner table, and, conſequently, that making a perforation there could be of no ſervice. See Eſſay on Injuries of the Head, p. 32—34.

We ſhall next enumerate the ſymptoms of preſſure on the brain, and contraſt them with thoſe of concuſſion. It is to be underſtood, that the complaints produced are nearly the ſame, whether the preſſure is made by an extravaſation, or a fracture of the cranium with depreſſion.

Symptoms of Preſſure.

1. Patient at firſt ſtunned, with cold extremities.
2. Revives, and has an interval of ſenſe, in caſes of extravaſation, but not in thoſe of a depreſſed fracture.
3. The quantity of effuſed blood increaſing, he becomes drowſy and ſtupid.
4. Pulſe regular and ſlow.
5. Patient quite inſenſible.
6. Pupil dilated.
7. Stertorous reſpiration.

N.B. When the bleeding is very copious in the firſt inſtance,

ſtance, or when a violent concuſſion of the brain has alſo happened, the patient has no interval of ſenſe.

Symptoms of Concuſſion.

First ſtage.
- 1. Patient at firſt ſtunned.
- 2. Extremities cold; pulſe hardly perceptible.
- 3. When the violence has not exceeded a certain degree, the ſenſes return gradually.
- 4. The ſtomach rejects its contents; ſickneſs betrays irritability in the œſophagus and ſtomach, and cannot be expected, when the brain is labouring under much compreſſion, the great effect of which is to produce an univerſal inſenſibility, or palſy, throughout the body.
- 5. The pulſe is now ſlow, and intermits.

Second ſtage.
- 6. In proportion as the immediate effects of the ſhock of the brain ſubſide, ſymptoms of irritation and inflammation of that organ come on.
- 7. Symptomatic inflammatory fever begins.
- 8. Pupil of the eye contracted.
- 9. The veſſels of the eye become red and turgid.
- 10. Delirium.
- 11. Pulſe very frequent and ſmall.

We ſhall not expatiate on this ſubject; but refer to Compression, Concussion, Injuries *of the* Head, and Trepanning, for further information.

Extravaſation of blood in the thorax.—In caſes of wounds which penetrate the cavity of the cheſt, the intercoſtal arteries are liable to be injured, and if the blood cannot readily flow outward through the wound, it is apt to inſinuate itſelf between the pleura and lungs. An extravaſation of blood may alſo occur in the thorax, when ſome of the veſſels of the lungs, one of the coronary arteries of the heart, or the internal mammary artery, have been wounded. An effuſion of blood in the cheſt may likely obviouſly originate from a wound of the auricles, or ventricles of the heart, or of the thoracic aorta, and vena cava; but we need hardly obſerve, that in theſe and other inſtances, in which the bleeding would be in a moment exceſſively profuſe, the extravaſation proves inſtantly fatal. Smaller veſſels are frequently injured, and pour out a conſiderable quantity of blood in the cheſt; yet the records of ſurgery evince, that theſe accidents do not always have a fatal termination.

The ſymptoms commonly enumerated by ſurgical writers, as indicative of an extravaſation of blood in the thorax, are the following: the patient is greatly oppreſſed, and experiences a kind of uneaſineſs which will not let him remain for any length of time in the ſame poſture. He feels conſiderable difficulty in ſitting up in bed, except his body be bent a good way forward, in which poſition the diaphragm is relaxed, and not ſo much dragged by the weight of the extravaſated fluid. When the thighs are bent, the patient can lie with tolerable eaſe on his back, he is alſo not averſe to lying on the ſide on which the wound is ſituated; but he cannot place himſelf on the oppoſite one, without feeling very acute pain in the ſituation of the mediaſtinum.

His reſpiration is ſhort, frequent, and interrupted by ſighs; his veins become empty, a mortal paleneſs ſpreads over his countenance; his extremities become cold; a viſcid perſpiration covers his neck and temples; his teeth chatter, his pulſe grows weak, and if (as moſt frequently happens) the lungs are wounded, he coughs up frothy blood, and air iſſues from the wound.

The preceding claſs of ſymptoms, however, are not always attendant on every conſiderable effuſion of blood in the thorax. Wounded perſons have been known to die of ſuch an extravaſation, whoſe reſpiration was tolerably free, and who did not complain of ſuffering more inconvenience in one poſture than another. Sabatier ſtates, that ſeveral facts of this kind have fallen under his own obſervation. Other wounded perſons alſo, who have had moſt of the complaints, uſually imputed to extravaſations of blood in the thorax, have been cured by ordinary means.

The ſymptoms of an extravaſation of blood in the thorax are upon the whole very equivocal. Hence, ſeveral attentive practitioners have taken extraordinary pains to diſcover additional circumſtances, by which the nature of the caſe might be more infallibly aſcertained. Theſe endeavours, however, ſeem to have been attended with little ſucceſs. A ſurgeon of the name of Valentine aſſerted, that a ſort of ecchymoſis of the integuments, over the angles of the ribs, was an invariable ſymptom; but ſucceeding obſervers have not found the remark correct.

When there is no doubt in the practitioner's mind that blood is extravaſated in the cavity of the thorax, and that it is the occaſion of a dangerous oppreſſion of the lungs and diaphragm, the obvious indication is to endeavour to promote the eſcape of the effuſed fluid. However, before undertaking any operation, the revived ſtate of the pulſe, the return of warmth in the extremities, and the ceſſation of convulſions ought to denote, that the hemorrhage no longer continues from the wounded veſſels. If vent were given to the extravaſation before the bleeding had ceaſed, a freſh quantity of blood would ſoon be poured out in the cheſt, and the patient die exhauſted.

For another reaſon, alſo, prudence requires that the practitioner ſhould not precipitately have recourſe to an operation: *viz.* allowing a little while gives nature an opportunity of employing her own reſources, and any one who will be at the trouble of referring to books of ſurgical caſes, will ſoon meet with examples in which there is every reaſon to believe that there was more or leſs blood extravaſated in the cheſt, though the patients completely recovered without any operation.

There are five principal methods of diſcharging blood from the cavity of the cheſt. 1. By placing the patient in a poſture which favours the eſcape of the blood. 2. By introducing a ſyringe for the purpoſe of ſucking it out, or a mere cannula, through which it is to flow. 3. By enlarging the wound. 4. By employing injections, with which the clots of blood are to be waſhed away. 5. By making an opening into the thorax in a depending ſituation.

Having thus curſorily treated of extravaſations in the cheſt, we ſhall quit the ſubject for the preſent, intending to reſume the conſideration of it in ſpeaking of wounds of the thorax. See Wounds.

For an explanation of the method of making a depending opening into the cheſt, ſee Paracentesis.

Extravaſations in the Abdomen.—Various kinds of fluids may be extravaſated in the abdomen in caſes of wounds, ſloughing of the inteſtines, &c. Bile, chyle, urine, blood, feces, &c. are all apt to be effuſed under particular circumſtances. Surgeons uſed formerly to ſuppoſe, that whenever any fluid eſcaped from a veſſel, or bowel, into the general cavity of the peritonæum, it always became extenſively diffuſed among the convolutions of the inteſtines. The erroneous ſuppoſition ſeemed to be confirmed by facts, the moſt open to obſervation, and completely exempt from the poſſibility of miſtake. Practitioners ſaw that the water of dropſies, the pus of abſceſſes, which had burſt into the abdomen, as well as the chyle and feces, which had eſcaped through a wound, or other ſort of breach of an inteſtine, were invariably and univerſally diffuſed among the folds of the meſentery and bowels after death.

M. Petit (the ſon) firſt queſtioned the accuracy of the foregoing opinion, in relation to the patient while alive. He ſuggeſted that as in the living body the inteſtines were diſtended with feces, alimentary matter and air, while they were alſo mutually acting againſt each other, and in a continual ſtate of compreſſion from the alternate contraction of the diaphragm and abdominal muſcles, there might be a ſuperior reſiſtance made to the weight of the extravaſated fluid tending to ſeparate the viſcera to which we allude. On the contrary, ſays Petit, is it not poſſible that, as ſoon as the patient is dead, and the above kind of reſiſtance is taken away, the extravaſated fluid may inſinuate itſelf any where without difficulty? M. Petit remarks, that the truth of the preceding ſuggeſtion cannot be doubted, when we conſider, that certain caſes of hernia get well, notwithſtanding the burſting of the gangrenous part of the inteſtine, after its reduction into the abdomen. In ſuch inſtances, in fact, the contents of the bowels appear to eſcape outward through the wound entirely in conſequence of the reſiſtance made to their diffuſion among the convolutions of the inteſtines. However it might be objected, that, in caſes of hernia, ſince the bowel is almoſt always adherent to the edge of the abdominal ring, the iſſue of the inteſtinal matter through the wound is rather to be aſcribed to the eaſe with which this event may happen, than to any reſiſtance made internally by the ſurrounding viſcera. But M. Petit cites ſeveral caſes, which fully confirm, that there is a vaſt reſiſtance made to the lodgment of extravaſated fluids among the convolutions of the bowels, and folds of the meſentery.

After death, any fluid, extravaſated in the abdomen, may by its mere gravity inſinuate itſelf any where, and become diſperſed among the various parts, becauſe theſe parts being without action make no oppoſition. But in the living ſtate, all the abdominal viſcera reciprocally act upon each other, and forming, as it were, only one body, by reaſon of ſuch mutual ſupport, the reſiſtance which is made to any extravaſated matter will always keep it from becoming widely diffuſed, in the manner which many have imagined.

Let us next, with M. Petit, reflect upon the inferences to be drawn from ſuch reciprocal action of the abdominal viſcera.

The firſt conſequence is, that an extravaſated fluid can only inſinuate itſelf into the cavity of the abdomen, in the ſame way that a fluid becomes effuſed in an external part; that is to ſay, the extravaſation can only ſpread by degrees, and ſucceſſively, into ſuch places as offer the leaſt reſiſtance. Blood, when it inſinuates itſelf into the interſtices of the muſcles, can only get from one membranous cell into another, by the firſt one being ſo diſtended, that the fluid can more readily get into a ſecond cell, and from this into a third, than increaſe the diſtended ſtate of its firſt ſituation. Juſt ſo in the abdomen, the blood which eſcapes from a wounded veſſel, is firſt effuſed into a ſituation near the opening in the veſſel, either between the peritonæum and ſurface formed by the inteſtines, or more deeply among the convolutions of the bowels, or ſome of the folds of the meſentery. In the proportion as the bleeding continues, the blood forces its original boundary, and dilates the place which it occupies, in every direction, until it meets with leſs reſiſtance in making its way, either upward or downward, or to the right or left. The extravaſation continues to dilate the new ſpace, which it fills in the ſame way, until either the firſt limits are forced, or the effuſed fluid ſpreads in ſome other direction. The extravaſation will expand in this manner, till the reſiſtance, made by the viſcera, becomes equal to the impetus, with which the blood iſſues from the veſſel. M. Petit was of opinion, that it was this kind of reſiſtance which put a ſtop to the hemorrhage, even before any coagulum had been formed in the opening of the veſſel. That the blood, while flowing from the veſſel and in a fluid ſtate, ſhould only make one maſs and be contained in one cavity, till coagulation takes place, is a circumſtance which cannot rationally be imputed to any thing elſe, than the reſiſtance depending upon the mutual action of the viſcera in the living ſtate. It is alſo equally certain, that it is in conſequence of the ſudden ceſſation of ſuch reſiſtance, that extravaſated blood, which is fluid after death, becomes diſperſed among the different convolutions of the bowels, and forms numerous ſcattered collections.

The ſecond inference which M. Petit mentions, as deducible from the reſiſtance ariſing from the reciprocal preſſure of the abdominal viſcera, is that an extravaſation in the cavity of the abdomen cannot ſo eaſily happen, as ſome have fancied. It was once not an uncommon idea, that a breach in a very moderate veſſel could occaſion a conſiderable extravaſation, becauſe the orifice could not be compreſſed, like that of a veſſel in a more external ſituation. It is indeed true, that no compreſſion can be directly applied to the opening in an internal veſſel; but the reſiſtance which the ſurrounding viſcera make to the extravaſation, operates as a ſubſtitute. It is even probable, according to Petit, that when blood is effuſed in the abdomen, it has a greater reſiſtance to overcome, than when extravaſated in an external part. This author ſtates, that the reſiſtance of the cellular membrane, the common bond of connection between the muſcles, is undoubtedly leſs than that which depends on the reciprocal action of the inteſtines, and reſt of the viſcera. The inceſſant alternate motion of the abdomen and thorax is in favour of the preceding opinion. The facility alſo, with which abſceſſes ſituated in the abdomen are diſcharged, through a ſmall, and very frequently not a depending opening, is an additional fact, proving that the abdominal viſcera, by the manner in which they mutually preſs upon each other, make a greater reſiſtance to an extravaſation, than can be made by the cellular ſubſtance in other parts of the body.

Swords have often been thruſt completely through the body, without giving riſe to any dangerous ſymptoms, or only to ſuch as frequently attend wounds, which do reach into the cavity of the belly. We cannot imagine, contrary to all probability, that, in this caſe, the weapon has ſlipped over the inteſtines, through their interſtices, and by good luck has wounded none of the blood-veſſels. We muſt rather conclude, that an extravaſation does not always enſue from a wound of the viſcera or blood-veſſels, or at leaſt, that the extravaſation is not invariably attended with ſuch conſequences as former practitioners uſed to ſuppoſe.

For the purpoſe of rendering the foregoing remarks more intelligible, let us follow M. Petit in his obſervations, and take notice of the principle which he has laid down in his excellent memoir, *viz.* that without a particular action in the muſcular fibres of the inteſtine or artery, no extravaſation would occur in the abdomen, even were there a breach in ſuch bowel or veſſel. Suppoſing the blood veſſels deſtitute of action, and the place of the opening preſſed upon by a force equal to that, which operates upon the reſt of their extent, the fluid, which they contain, would never be effuſed in the abdomen, ſo as to form an extravaſation. Beſides its being evident, that this muſt be the fact, M. Petit mentions his having actually obſerved it in the body of a man, who died of gangrene in the abdomen, in conſequence of a hernia, which was attended for upwards of a fortnight with the moſt violent ſymptoms of ſtrangulation. Nearly the whole of the inteſtinal canal was equally affected with gangrenous miſchief, ſo that it was ſcarcely poſſible to handle any of the bowels without occaſioning a breach in them. However, although the inteſtines were filled with very fluid excrement, none of it was extravaſated in the abdomen. In ſeveral places, indeed, Petit diſcovered numerous little breaches of continuity, which had allowed a little of the excrement to eſcape, but only juſt enough to tinge the adjacent parts. Petit acknowledges, at the ſame time, that round where theſe holes were ſituated, ſome ſlight adheſions had taken place between the bowels, and theſe and other parts; but they were ſo weak, and eaſily broken, as to be quite incapable of hindering an extravaſation. Petit concludes, that in this inſtance no extravaſation happened, becauſe the inteſtinal canal was every where affected with gangrene in nearly the ſame degree, and the diſeaſe had deſtroyed the tone and action of the muſcular fibres of the inteſtines.

It is contended by Petit, that the foregoing caſe affords ſufficient proof, that, without a contractile power in the blood veſſels and inteſtines, no extravaſation of their contents could be produced in the abdomen, and that ſuch an event would certainly be oppoſed by the action of the abdominal muſcles and diaphragm, which make uniform and equal preſſure upon all the viſcera. If this ſtatement be correct, it is obvious, firſt, that the greater the action of the wounded veſſels is, in relation to the quantity of fluid which they have to propel, the greater will be an extravaſation from them: ſecondly, that no extravaſation can ariſe unleſs the action of the veſſels themſelves be capable of overcoming the reſiſtance depending upon the mutual action of the parts. Hence, only wounds of veſſels above a certain ſize can give riſe to extravaſations, at leaſt, to any of importance. The veins cannot occaſion ſo much extravaſation as the arteries: nor are wounds of the inteſtines ſo apt to be followed by an effuſion of the chyle and feces, as the ſame injuries of the blood veſſels are liable to be attended with an extravaſation of blood. Petit was alſo of opinion, that wounds of the ſtomach were not ſo often as thoſe of the bowels the cauſe of this kind of accident.

The feces cannot be ſo eaſily extravaſated as blood, not only becauſe the action of the inteſtines, particularly that of the ſmall ones, upon their contents, is weaker than that of the blood veſſels upon the blood, but, principally, becauſe, when there is a breach in one of the bowels, the contents will continue their courſe through the inteſtinal canal, without any need of there being a conſiderable obſtacle to the occurrence of an effuſion. However, Petit admoniſhes us not to conclude, from what has been ſaid, that the chyle and feces can never be extravaſated in the abdomen. There is no doubt whatever, he obſerves, that an extravaſation may take place, when the wound in the bowel is of ample ſize, the gut filled with chyle or excrement, and care is not taken to empty the large inteſtines very often with glyſters. The event may alſo happen, when pain and irritation render the muſcular action of the inteſtines violent, irregular, and convulſive, and when unequal preſſure is made upon the abdomen. Under ſuch circumſtances, the reſiſtance made to an extravaſation, by the reciprocal action of the viſcera, is overcome, and the contents of the bowels will continue to be effuſed, until the impulſe ariſing from the contractile power of theſe organs returns to a ſtate of equilibrium with the reſiſtance depending on the mutual action of all the viſcera.

The extravaſation of chyle and feces does not take place differently from that of blood; but in wounds of the bowels there is this advantage, that the ſame opening which has given paſſage to the extravaſated fluid, may alſo allow it to return and paſs off. Petit remarks that we need no further proof of what has been ſtated, than the great evacuations of blood, which ſome wounded perſons have had with their ſtools, without being afflicted with any of the ſymptoms of extravaſation. It is highly improbable, that ſuch bleeding could depend upon the injury of any of the veſſels ramifying upon the inteſtinal canal, ſince their ſize is too inconſiderable. We rather believe that, in theſe caſes, ſome veſſels, either of the meſentery, or ſome other part, have been wounded at the ſame time as the inteſtine, and that the blood has inſinuated itſelf into, and taken its courſe through the bowels, in conſequence of the reſiſtance made to its extravaſation among the viſcera.

The foregoing remarks, made by Petit (the ſon), clearly prove not only that an extravaſation of feces cannot ſo eaſily happen in the abdomen as has been imagined; but, alſo, that it is leſs dangerous than an effuſion of blood uſually is, and that it is accompanied by leſs violent ſymptoms. When the contents of the bowels are extravaſated, adheſions are likewiſe obſerved to form more readily, and to limit the effuſed matter ſooner, than when the extravaſation conſiſts of blood. After ſuch adheſions have once formed, it is probable that the extravaſated matter may be got rid of in the ſame favourable way, as certain abſceſſes, which have diſcharged themſelves into the inteſtinal canal. Blood, however, cannot inſinuate itſelf again into the canal of the veſſel, out of which it has eſcaped, becauſe a clot blocks up the opening. But a wound in an inteſtine remains continually open, till it is cloſed by the adheſions which the bowel contracts to the adjacent parts: adheſion, indeed, is the only means by which a wound of this deſcription can be healed.

M. Petit remarks, that among the numerous facts which might be adduced in proof of the difficulty with which a wound of the ſtomach permits the aliment to be extravaſated, the operation of an emetic in this caſe is a ſtriking one. Petit expreſſes his belief, that vomiting does not depend upon the action of the muſcular fibres of the ſtomach, but entirely upon the ſudden and violent contraction of the abdominal muſcles. This author conceives, that, if the particular action of the ſtomach itſelf had much concern in the production of vomiting, an extravaſation of the alimentary matter would neceſſarily happen in the abdomen when that viſcus is wounded. However, in the inſtances referred to by Petit, the occurrence did not take place, becauſe, notwithſtanding the violence with which the abdominal muſcles and diaphragm contracted, they made equal and uniform preſſure on all ſides of the ſtomach. The danger of an extravaſation is alſo leſs, inaſmuch as a wound of the ſtomach is always much ſmaller in relation to its cavity, than that of a bowel, in regard to the inteſtinal canal.

Circumſtances are very different, in reſpect to wounds of the gall and urinary bladders, eſpecially when theſe receptacles are full. An extravaſation is then an inevitable conſequence, both on account of the great fluidity of the bile and urine, and of the contractile power with which the parts are endued, and againſt which the action of the abdominal muſcles makes no ſort of reſiſtance. An extravaſation of theſe fluids is extremely dangerous, by reaſon of their irritating quality with reſpect to the viſcera. The co-lies and irregular contractions which ſuch ſtimulating fluids excite, cauſe the extravaſation to become more widely diffuſed. The eaſe alſo, with which the bile and urine mix with the ſerum, that naturally moiſtens the ſurfaces of all the viſcera, leads us to ſuſpect, that whenever thoſe fluids are extravaſated, they very ſoon become univerſally diſperſed among all the convolutions of the inteſtines.

Againſt theſe latter extravaſations little can be done, and unleſs they are in ſmall quantity, and their increaſe can be prevented, the patient's life hardly admits of being ſaved. Leaving a catheter in the bladder, indeed, is a ſure means of hindering the extravaſation of urine from augmenting; but not much confidence can be placed in the kind of outlet afforded by the duct of the gall-bladder.

When the extravaſated matter is completely encyſted and circumſcribed, it happens, that as ſuch matter had to overcome the reſiſtance of the parts before it could be effuſed, no ſooner is a paſſage afforded for its eſcape, than the reaction of the ſeparated parts neceſſarily forces out whatever fluid has inſinuated itſelf between them. This is a third conſequence, which is pointed out by Petit as reſulting from the reſiſtance, made by the reciprocal action of the abdominal viſcera, to extravaſations.

The foregoing obſervations tend to ſhew, that an extravaſation in the abdomen, and eſpecially one of blood, may be as completely diſcharged as a collection of fluid in the thorax. The evacuation, at leaſt, may always be eaſily effected, when the extravaſation is bounded at any part by the parietes of the abdomen: a circumſtance, which muſt invariably occur, whenever the extravaſation is conſiderable. Indeed Petit informs us, that it was always the caſe, as far as his experience went even when the effuſion was not very copious.

It is not enough to make ſurgeons underſtand, that fluids, extravaſated in the abdomen, admit of being diſcharged by an operation; we deem it alſo neceſſary to explain the ſymptoms denoting the caſes in which ſuch a proceeding is proper.

In order to underſtand this intereſting part of the ſubject, Petit, and moſt ſurgical writers after him, have adviſed us to draw a diſtinction between the conſecutive ſymptoms and the primary ones, or thoſe which attend the wound from the firſt, and are, ſtrictly ſpeaking, proper to it, becauſe they depend eſſentially upon the diviſion of the injured parts. Such breach of continuity occaſions, from the firſt, pain, irritation, tenſion, convulſions, and ſwelling and inflammation of the abdomen, affections naturally leading to other conſecutive ſymptoms, which vary according to the injured parts, and the degree of inflammation. Of the latter claſs are, hiccough, vomiting, conſtipation, ſuppreſſion, or retention of the bile and urine, a great deal of fever generally at firſt, and, after the inflammation has attained a certain pitch, a concentration and ſinking of the pulſe, conſiderable proſtration of ſtrength, and cold ſweats.

If when the firſt train of ſymptoms has been relieved, and after an interval of from four to eight days or more, the ſymptoms recur, or become exaſperated, without any apparent cauſe, we may infer that ſuch conſecutive complaints depend upon an extravaſation.

It may at firſt ſeem extraordinary, that the ſymptoms of an extravaſation of blood ſhould be conſecutive; for, as the effuſion takes place at the moment, when the wound firſt happens, why do not the ſymptoms commence at the ſame time?

Petit has referred the reaſon to the following circumſtances: blood, extravaſated in the abdomen, does not give riſe to any complaints, either by the preſſure which it makes, or by its quality; and whenever any ſymptoms are occaſioned on the firſt occurrence of the effuſion, they are thoſe of weakneſs, depending on the loſs of blood to the circulation. The extravaſation afterwards becomes entirely circumſcribed by the adheſions, which are produced by the inflammation around. An additional quantity of fluid continues to be ſecreted from the veſſels into the encyſted cavity of the effuſed blood, and conſequently pain, inflammation, &c. are occaſioned by the increaſing diſtention, now produced.

We ſhall not ſtop to enquire into the accuracy of the latter part of the foregoing ſtatement, as the fact, that the ſymptoms of an extravaſation are conſecutive, is a piece of information highly important to the practitioner, while the theory of the ſubject is a ſubordinate conſideration.

The remainder of the remarks, reſpecting extravaſations in the abdomen, and their treatment, will be found in the article WOUNDS. Some obſervations will alſo be offered, when we ſpeak of HERNIA.

EXTRAVASATION is a term ſometimes likewiſe uſed by the gardeners in ſpeaking of gums, juices, &c. which ouſe out of their trees either ſpontaneouſly, or at inciſions.

EXTREAM, or EXTREME, is applied to the laſt and outermoſt part of any thing; or that which finiſhes and terminates it on that ſide.

The extreams of a line are points. There is no paſſing out of one extream into the other, without going through the middle. Extream remedies muſt only be had recourſe to in extream neceſſity.

Some anatomiſts apply the denomination extremes, or extremities, to the arms and legs. See EXTREMITIES.

EXTREAMS, in *Logic*, denote the two extream terms of the concluſion of a ſyllogiſm, *viz.* the predicate and ſubject.

They are called extreams, from their relation to another term, which is a medium or mean between them.

The predicate, as being likewiſe had in the firſt propoſition, is called the *majus extremum*, greater extream; and the ſubject, as being put in the ſecond, or minor propoſition, is called the *minus extremum*, leſſer extream.

Thus, in the ſyllogiſm, man is an animal: Peter is a man, therefore Peter is an animal; the word animal is the greater extream, Peter the leſs extream, and the man the medium. See SYLLOGISM.

EXTREAM *and Mean Proportion*, in *Geometry*, is when a line is ſo divided, that the whole line is to the greater ſegment, as that ſegment is to the other.

Or, as Euclid expreſſeth it, when the line is ſo divided, that the rectangle under the whole line, and the leſſer ſegment, is equal to the ſquare of the greater ſegment.

The invention of this diviſion is thus: let the given line be $AB = a$ (*Plate* VII. *Geometry. fig.* 87.) and for the greater ſegment put x, the leſſer will be $a - x$. Then, by the hypotheſis, $a : x :: x : a - x$. Therefore, $aa - ax = xx$, conſequently $aa = ax + xx$. And, by adding $\frac{1}{4}aa$ on each ſide, to make $xx + ax + \frac{1}{4}aa$, a complete ſquare, the equation will ſtand thus, $\frac{5}{4}aa = xx + xa + \frac{1}{4}aa$.

Now, ſince the latter is exactly a ſquare, its root $x + \frac{1}{2}a = \sqrt{\frac{5}{4}aa}$, and by tranſpoſition it will be $\sqrt{\frac{5}{4}aa} - \frac{1}{2}a = x$; which laſt equation is a canon for finding x.

For at the foot of $AB = a$, ſet at right angles $CB = \frac{1}{2}a$; then draw CA, the ſquare of which is equal $ABq + CBq = \frac{5}{4}aa$. And therefore $AC = \sqrt{\frac{5}{4}aa}$; make $CD = CA$. From whence $CB = \frac{1}{2}a$ being taken as the caſe requires, there remains $BD = x$; which transferred into AB, ſhall give the point E, where AB is cut according to extream and mean proportion.

This cannot be exactly done in numbers; but if you would have it tolerably near, add together the ſquare of any number, and the ſquare of its half, and extract, as near as you can, the ſquare root of the ſum; from whence taking half, the remainder is the greater part.

Extreams, in right-angled ſpherical trigonometry. When one of the five circular parts of a right-angled ſpherical triangle, *viz.* the three ſides and two oblique angles, (for the right-angle is neglected) is pitched upon for the middle term, then the two circular parts lying immediately next to it are called extreams conjunct; and the two parts remote from the aſſumed middle part, or not immediately next it, extreams disjunct. See Circular *Parts*, Triangle, and Trigonometry.

Extream *Unction*, one of the ſacraments of the Romiſh church, the fifth in order, adminiſtered to people dangerouſly ſick, by anointing them with holy oils, and pronouncing ſeveral prayers over them.

It is called extream unction, as being only given to perſons in extremity. In the thirteenth century, it was called the "unction of the ſick," and not extream unction: for, in the earlier ages, it was given before the viaticum; which practice, according to F. Mabillon, was not changed till the thirteenth century.

The reaſons he aſſigns for the change are, that in that age there aroſe divers miſtaken opinions, ſeveral of which we find mentioned and condemned in the Engliſh councils; among the reſt, it was held, that ſuch as had received this ſacrament, in caſe they recovered, might not make uſe of their wives, nor eat meat, nor go barefooted; whence they choſe to forbear it till the laſt extremity, which practice prevailed. See the Councils of Worceſter and Exeter, in the year 1287; that of Wincheſter, in 1308; and F. Mabillon, Acta Sanct. Benedict. Sæc. iii. p. 1.

The form of extream unction is now deprecative, as the divines call it; formerly it was abſolute and indicative. This ſacrament is not only in uſe in the Latin, but alſo in the Greek church, and throughout the Eaſt, though under another name, and with ſome difference in the circumſtances; in that the orientals do not wait till their ſick are come to extremity, in order to anoint them; but the ſick generally go to church themſelves; and it is adminiſtered to them as often as they are indiſpoſed: the Greeks taking that direction of St. James, chap. v. ver. 14. which is the foundation of the practice, in a general ſenſe: "Is any ſick among you? let him call for the elders of the church, and let them pray over him, anointing him with oil." F. Dandini diſtinguiſhes two kinds of unction among the Maronites: the one called unction with the oil of the lamp; but this, he ſuggeſts, is not the ſacramental unction ordinarily adminiſtered to ſuch as are in extreme ſickneſs; becauſe the oil is only conſecrated by a prieſt, and it is given to all who are preſent; not to the ſick only, but alſo to the healthy; even the prieſt who officiates partakes of it. The other kind of unction, according to that father, is only for the ſick; this is performed with oil conſecrated by the biſhop alone, on Holy Thurſday; and this, it ſeems, is the ſacramental unction.

The unction with lamp-oil is in uſe, not only among the Maronites, but throughout all the Eaſtern church, who uſe it very religiouſly. The truth is, they do not ſeem to have any other ſacrament of extream unction beſide this. Yet F. Goar obſerves, though it be only a ceremony, with regard to thoſe in health, it is a real ſacrament to thoſe that are ſick.

In their great churches they have a lamp, wherein this oil for the ſick is preſerved; this lamp they call κανδηλα του ευχελαιου, that is, *the lamp of oil joined with prayer*; for what the Latins call extream unction, the Greeks call ευχελαιον, or αγιον ελαιον, that is, *oil with prayer*, or *holy oil*.

Extreme, in *Muſic*, is applied to ſuch intervals as deviate as much as poſſible from the true chord of the ſame name, without changing their names; generally when the term extreme is added to the prefix diminiſhed or ſuperfluous (which denote a minor ſemitone), its effect is to double that diminiſhing or ſuperfluous effect, or to make it $\frac{576}{625} = 72\Sigma + 2f + 6m$; but ſometimes we find Mr. Orwend applying a major comma and a minor ſemitone as the effect of his term extreme, or $\frac{128}{135} = 47\Sigma + f + 4m$, = the medius ſemitone: at other times we find extreme, when added to other prefixes, to have different effects, as extreme ſharp intervals, for inſtance, are ſometimes found a minor ſemitone above the intervals reſpectively, or $\frac{24}{25} = 36\Sigma + f + 3m$: but in other inſtances the ſame prefix ſignifies a major comma more, or $\frac{128}{135} = 47\Sigma + f + 4m =$ the medius ſemitone. It were much to be wiſhed that theſe various applications of terms, ſo perplexing to a reader, could be got rid of, and a conſiſtent nomenclature in harmonies adopted.

EXTREMITIES, in *Anatomy*, is a term applied to the limbs, as diſtinguiſhing them from the other diviſions of the animal body, the head, and trunk. They are immediately connected with the latter by one end, and totally free in all other parts. The numerous varieties of their form depend partly on the bones, which enter into their compoſition; but, in a material degree alſo, on the ſoft parts which ſurround theſe, and which give to the limbs that roundneſs and elegance of figure, in which beauty is united with activity and ſtrength. The extremities, being eſſentially concerned in all the functions of animal life, and conſtituting the great agents of locomotion, are compoſed of organs eſpecially deſtined for theſe purpoſes. Their volume is formed by bones and muſcles, ſupplied by numerous veſſels, and communicating with the common centre of ſenſation, the brain, by nerves diſtributed moſt extenſively; producing, in one part, the moſt important ſenſe of touch, and giving the ſpring in all to rapid and varied motions.

The extremities are four in number, divided in man into upper and lower; in other animals into anterior and poſterior. Each extremity is divided into four parts; the upper into the ſhoulder, the arm, the fore-arm, and the hand; the lower into the hip, the thigh, the leg, and the foot. In treating of theſe, both ſeparately and generally, we ſhall conſider only the bones, and the connections between them. On theſe depend all the motions of the limbs, the direction and extent of action of the muſcles being wholly dependent on the bony points to which they are attached, and on the form and mode of junction of the bones on which they exert their power. The influence of any muſcle will be conſidered in the detailed deſcription of each, and may be eaſily applied to the ſubject immediately before us.

Our preſent plan is to offer, firſt, ſome general obſervations on the external figure of the bones of the extremities, as far as it relates to their uſes; on their modes of articulation and their motions. We ſhall next examine ſeparately and in detail each diviſion of the bones of the upper extremity, the ligaments connecting them, the mechaniſm of their articulations, and their individual motions; afterwards the combined movements of the ſeveral parts, and the powers of the member, as reſulting from this conſtruction, both in the paſſive and active ſtate. A ſimilar mode will be purſued in conſidering the lower extremity. We ſhall conclude with a compariſon between the upper and lower limbs as to ſize, figure, direction, motions, and growth.

The bones determine eſſentially the ſize, figure, and direction of the extremities, forming, by their aſſemblage, ſolid and flexible columns, capable of motion in very varied directions. Some of theſe in each column differ very widely in form; while others partake of the figure of both oppoſite varieties. We deſcribe them under the different names of long, of broad or flat, and of ſhort bones.

In the limbs the bones diminiſh ſucceſſively in length and ſize, and increaſe in number, as we deſcend from the trunk to the oppoſite extremity, from the arm, or thigh, to the fingers or toes. In conſequence of this arrangement the upper part of the limb enjoys extenſive motions, whilſt the lower is characterized by multiplied, but confined movements. Theſe bones have every where an analogous ſtructure, being broad and voluminous at their *extremities*, contracted, and frequently rounded in their middle part, or *body*. The increaſed volume of the extremities poſſeſſes the double advantage of enlarging the articular ſurface, and thereby diminiſhing the chances of diſplacement, and of preſerving the ſymmetry of the limb. We perceive, for inſtance, that the bellies of the muſcles correſpond to the middle or ſmalleſt part of the bone, while the flat and contracted tendons are fixed near the protuberant extremities. The augmentation of ſize, in the ends of the long bones, is by no means ſudden; it commences inſenſibly from the body. We remark, on theſe extremities, various eminences, ſubſervient to the purpoſes of articulation, or giving an advantageous attachment to tendons. The middle part, or body, is generally ſmooth, offering prominent lines for muſcular or tendinous attachments. Theſe, where ſtrongly marked, deſtroy the cylindrical form of the bone: they are uſually three in number, longitudinal, ſeparated by plane ſurfaces, and give the bone a priſmatic figure, as may be obſerved in the arm, fore-arm, and leg. In theſe inſtances a ſection of the bone is manifeſtly triangular; yet its internal canal preſerves a circular form. We may obſerve alſo, that the body, in nearly all the long bones, appears as if twiſted on itſelf; ſo that the direction of the upper end differs more or leſs from that of the lower. This is rendered evident, by tracing the oblique courſe of the prominent lines between the two extremities; for example, in the bone of the arm.

The long bones are formed from three points of oſſification. The firſt of theſe is obſerved in the centre of the body, extending on each ſide to the extremities, at which the bony cylinder is arrived at the period of birth. Soon after this time, a point of bone is perceived in the centre of each cartilaginous extremity, which increaſes gradually, advancing towards the body, with which it at laſt unites. From this conſideration of the figure and formation of the long bones, we may naturally derive the arbitrary diviſion into a *body* and two *extremities;* which diviſion we ſhall adopt throughout. The body of the bone is the *diaphyſis* of ſome Latin writers; and the two ends being at firſt united to the body only by cartilage, are called *epiphyſes*.

The broad bones are not found ſo generally in the extremities as thoſe of the long form; we obſerve them only at the part immediately united with the trunk, where they offer an ample ſpace for the attachment of the powerful muſcles concerned in moving the limb. In our deſcription we obſerve two *ſurfaces* and a *circumference*. The former, if they give attachment to muſcles, are uſually unequal and rough; the latter is thicker than the middle of the bone, offering more points of origin to muſcular fibres, as we may obſerve in the margin of the hip bone.

The ſhort bones of the extremities are found in ſituations where it was requiſite to unite a certain degree of mobility with firmneſs, as, for inſtance, in the foot. They are collected in conſiderable number in the regions which they occupy; and have numerous eminences and depreſſions on their external ſurfaces, neceſſary for their reciprocal articulations and for the inſertion of the connecting ligaments. Nothing can be more irregular than their figure, which, in addition to their comparative ſmallneſs and number, has given riſe to much ambiguity of deſcription. By conſidering them under the ſame aſpects as the other bones, and by carefully noticing their relations to theſe, all confuſion may be avoided. The ſhort bones, in general, continue longer in a cartilaginous ſtate than the others, reſembling, in the phenomena of their oſſification, the epiphyſes, or extremities of the long bones.

There ſtill remain ſome ſmall bones, found only in the extremities, which can hardly be included in either of the above claſſes, and are diſtinguiſhed by the epithet of ſeſamoid. They poſſeſs this peculiarity, that they are formed, not in common cartilage, but in the middle of a tendon, or ligament, and that no trace of them can be obſerved in early life. Of their uſe we ſhall ſpeak hereafter.

There are ſome general characters belonging to all the above-mentioned claſſes of bones. We obſerve in all eminences and hollows, either giving attachment to muſcles, or ligaments, or forming ſurfaces for articulation. The eminences deſigned for the former purpoſe are very numerous in the bones of the extremities, and vary greatly in figure. They ſometimes appear only as aſperities impreſſed in the midſt of a ſmooth ſurface, giving origin to a number of diſtinct aponeurotic fibres; ſometimes as prominences or tubercles more or leſs elevated and rough, giving inſertion to one or more tendons; or, laſtly, as a continued raiſed line. In general theſe eminences are proportioned to the muſcles which are fixed to them; ſo that under which-ever form they appear, there is an equality of ſpace allowed for the tendinous inſertions of muſcles of equal bulk. They are in general leſs ſtrongly marked in the female than in the male; in the infant than in the adult; in feeble animals than in the carnivorous tribes, which live by preying on others. Their prominence is indicative of vigour and activity of motion; being more developed as the muſcles are more powerful. This is ſtrikingly exemplified by a compariſon of the bones of a well made and muſcular man, where the outline of each muſcle might be traced with energy and preciſion through the ſkin, with thoſe of a weak and ill proportioned male, whoſe rounded and faintly marked limbs, reſembling thoſe of the female, betray a total want of vigour or addreſs. The uſes of theſe eminences may be clearly traced to their removing the inſertions of muſcles farther from the centre, or axis of the bone, and conſequently increaſing their power of moving it. The eminences, which give attachment to ligaments, poſſeſs the advantage of removing the ligament farther from the joint, and thereby facilitating, and giving greater extent to its motions. Theſe eminences have received different names, according to their ſituation, their direction, or figure, as we ſhall ſee more particularly hereafter.

The hollows obſerved on the external ſurfaces of the bones, (with the exception of articular cavities, of which we ſhall ſpeak below,) are deſigned either for the attachments of muſcles, or for giving paſſage to their tendons. The firſt of theſe have the evident advantage of increaſing the ſurface, without augmenting the bulk of the bone;

the latter appear as gutters, or grooves more or leſs deep, lined by cartilage, and completed by very ſtrong ligamentous bands, through which the tendons glide in their way to their final attachments.

The connections between the bones of the extremities, whatever be their mode, are known by the general term of articulations. Their varieties have given riſe to numerous technical, and in ſome meaſure obſolete, names, for which we refer to the articles Joint and Diarthrosis. Some joints allow of motion in every direction; and we may trace a gradual decreaſe of mobility, through many intermediate ſteps, till we arrive at articulations which admit only of a gliding of the bones on each other. We have examples of the firſt in the joints of the ſhoulder and hip; where the extent of motion requires rounded articular ſurfaces, concave and convex in the oppoſite contiguous bones; conſtituting what is commonly termed the ball and ſocket joint. In man the moveable bone has the rounded head, the ſupporting bone the correſponding hollow. In ſome animals we have inſtances of a contrary diſpoſition, in which a concavity in the moveable bone moves in all directions on an oppoſite convex ſurface. This mode of connection is found only in the ſhoulder and hip; and one advantage reſulting from this ſtructure being found at the upper part of the limbs, is, that the whole member neceſſarily partakes of the ſame extenſive motions; while it allows of a greater firmneſs and ſolidity in the inferior articulations. The joints we have juſt mentioned are, in this ſenſe, the joints, not only of the bones of the arm and thigh, but of all the limb, the motions of which, conſidered as a whole, they eſſentially and principally influence. Hence, if their mobility is deſtroyed, either by accident or diſeaſe, the limb becomes uſeleſs: whilſt a ſimilar occurrence in the inferior joints produces a partial inconvenience only. By this arrangement alſo, the joint, which, from its want of firmneſs, is moſt liable to injury, is the furtheſt removed from the immediate action of external bodies.

The extent of motion decreaſes as we proceed towards the extremities of the limbs. We find no rounded head, whoſe axis makes an angle with that of the cylinder of the bone, but an articular ſurface placed directly at the top or bottom. Of this we have examples in the connection of the collar bone with the breaſt, of the fore-arm with the wriſt, &c. In theſe, all power of rolling the bone, which is enjoyed in a high degree by the thigh, and by the arm, is deficient. In the next ſtep, the motions are confined to flexion and extenſion, as in the elbow, the knee, and the middle of the fingers. In this diviſion the articular ſurfaces conſiſt of eminences and hollows adapted reciprocally to each other, allowing of motion in one direction only. They are remarkable alſo for their large extent, which imparts to them ſolidity; and for admitting a greater degree of motion in the direction of flexion, than in the oppoſite one of extenſion, as may be obſerved in the knee, elbow, and fingers. The degree of extenſion is always effectually limited, either by a projection of bone, as in the elbow; or by ſtrong ligaments, as in the knee, &c. In other inſtances, the articulation allows of rotation only; a convex ſurface turning in a concave, or a hollow ſurface rolling over a convex one; both of which may be ſeen in the motions of the bones of the fore-arm. In the laſt kind we obſerve only a gliding of plane articular ſurfaces on each other, more or leſs obſcure, limited on all ſides by ligaments binding the bones cloſely together. To make up for this very confined motion, we uſually find many ſuch joints united, producing in this ſtate a more ſenſible degree of motion than could poſſibly occur in any of them ſingly. This may be ſeen in the wriſt.

In all theſe articulations we find a ſmooth and poliſhed cruſt, of an elaſtic ſubſtance, called cartilage, on the ſurface of the correſponding bones, the immediate means of their motions on each other. It is ſuppoſed to obviate by its elaſticity the dangers reſulting from ſudden and violent ſhocks. The two correſponding cartilages of oppoſite bones are ſo diſpoſed as to touch at all points in ſome poſitions of the limb, whilſt in others they quit each other more or leſs, and are found oppoſite the ſoft parts ſurrounding the articulation. They are moulded into the form of the bone to which they adhere, preſerving its general figure. But in ſome caſes the cartilage is thicker in its middle than at the edges, thereby increaſing the convexity; in others the converſe may be obſerved, and the hollow of the articular ſurface is proportionably increaſed. Both occur in the hip and ſhoulder: the firſt in the heads of the thigh and arm bones, the laſt in the cavities which receive them, and in this manner the uniformity of contact is preſerved. In the other articulations the cartilaginous cruſts are nearly of equal thickneſs throughout.

The contact of the articular ſurfaces is ſecured by ligaments deſtined immediately for this purpoſe, and by the muſcles which paſs from one bone to another, ſupporting the joint either by the muſcular fibres, or their tendons. The ligaments are formed by very ſtrong fibres, a little elaſtic, diſpoſed in parallel lines, or interlaced in various directions. Their great reſiſtance inſures, at all times, more particularly when the limb is at reſt, the relations between the oppoſite bones; their ſituation limits in a great degree their inordinate motions. We obſerve them under many forms, and named either from theſe, or from their ſituation. Among the firſt are capſular ligaments, which are found ſurrounding ſome of the joints like cylindrical bags, embracing the oppoſite bones by the circumference of the two ends. Of this we have examples in the hip and ſhoulder, and nowhere elſe perhaps in the extremities. The ligamentous fibres are here interwoven and ſtrengthened by the adherence of the ſurrounding tendons, loſt at either extremity in the perioſteum, to which they are firmly united. The reaſon why capſular ligaments are found only in theſe articulations will be readily underſtood. They enjoy motion in every way nearly alike, and require on all ſides an equal degree of reſiſtance. Where, from the form of the articular ſurfaces, the motions are confined to narrower bounds, ligaments are neceſſary only in particular ſituations in order to regulate them. We find them in the other joints generally on the ſides, from which the name of lateral ligaments. Theſe are ſometimes rounded, ſometimes flat, interwoven with the perioſteum at each extremity, formed of fibres lying in parallel lines, or diverging at either end. There are other ligaments, not directly concerned in the joint, which ſtill ſtrengthen and regulate its motions, as may be remarked particularly in the ſhoulder. Beſides theſe we obſerve many irregular ſlips, or bands of ligaments, diſperſed here and there over the joint ſeparated by fat and cellular tiſſue from the neighbouring parts. The ligaments, of whatever deſcription, unite the oppoſite ſurfaces of bones, prevent their diſplacement, and yet allow of eaſy and rapid motions; a double advantage ariſing from their firmneſs on one part, from their flexibility on the other. They ſometimes give attachment to muſcles.

The muſcles ſurrounding the joints of the extremities are very powerful agents in ſecuring their contact, and the more ſo as their power increaſes in proportion as the chance of diſplacement is greater. The moſt vigorous efforts at diſplacement are made during violent and extended motions; at ſuch times the muſcles paſſing from bone to bone, and croſſing the articulation, are ſtrongly contracted, are firm in their contractions; and powerfully oppoſe the tendency which the extremities of the bones may have to abandon each other. In repoſe, when the muſcles are relaxed, and offer but little reſiſtance, the chances of luxation are few, but if they occur, the probability of its taking place is exceedingly increaſed.

In ſome joints of the extremities we find a ſubſtance of a ſomewhat cartilaginous ſtructure, occupying the interval between the cartilaginous ſurfaces, and called for this reaſon inter-articular cartilage. Such bodies are ſometimes moveable, as in the knee, correſponding to the varying want of uniformity in the articular extremities, or fixed more firmly to the end of the bone, or the neighbouring ligaments. They are elaſtic and highly flexible, reſembling cartilage in the firſt quality, the fibrous ligaments in the ſecond. This peculiarity of ſtructure has given riſe to the name of articular fibro-cartilages, a term beſtowed on them in recent times by the French anatomiſt Bichat.

Theſe ſurfaces are all moiſtened by a fluid, called ſynovia, on the compoſition of which we ſhall not dwell here. It is ſecreted by a delicate membrane which completes the ſtructure of the joint, by lining every part of its ſurface: whatever be the figure of the cartilages, or the ligaments, from both of which it is diſtinct, it adheres cloſely to them. It forms a bag without an opening ſpread over the whole organ, reflected from the cartilages to the ligaments or tendons; ſo that whatever it embraces is, in reality, without the articular cavity as it is termed, though projecting into it. To the whole it gives that ſmooth, poliſhed ſurface ſo neceſſary for the eaſy and rapid movements the articulations enjoy, at the ſame time ſecreting the fluid which facilitates them; it gives to the joint alſo its peculiar ſhining character.

The moſt ſimple motion of articular ſurfaces, common to them all, is gliding on each other in oppoſite directions; it is often ſo obſcure as to be ſcarcely perceptible. As we aſcend we find it multiplied in a variety of ways. The limb can be conſiderably bent, or extended; it can be removed from, or brought nearer to the axis of the trunk: the firſt of theſe motions is called abduction, the latter adduction; in ſome caſes, as in the ſhoulder, they are termed elevation, or depreſſion. The motions of ſome joints are confined to any two of theſe, as in the knee; others enjoy the whole, and all the intermediate degrees, as in the thigh. The union of theſe different movements, as exhibited in the arm or thigh, has been called circumduction. In this caſe the bone, inſtead of being moved in one direction, and back again to the oppoſite, is carried ſucceſſively through all, deſcribing by its extremity a circle, or the baſe of a cone, the apex of which is in the articulation above. Rotation, or rolling, is very different from this. In circumduction the bone is moved from its prior ſituation to a more diſtant one; in rotation it remains in the ſame place, it turns only on its axis, as may be obſerved in ſimply rolling the arm.

From this curſory review of the external characters of the bones of the extremities, of their modes of connection and motions, we proceed to the detailed deſcription of each. It will be neceſſary to premiſe, that in our terms of poſition and aſpect, we ſhall always ſuppoſe the body erect, the arms depending, and the hands ſupine, ſo that the little finger is in contact, or at leaſt next to the external ſide of the thigh. In this ſituation we ſhall ſuppoſe a vertical plane dividing the body into two halves, from before backward. With a clear impreſſion of this idea we ſhall find no difficulty or confuſion in the terms anterior and poſterior, ſuperior and inferior, external and internal, as applied to the different aſpects or ſurfaces of bones; by the latter, internal, we always mean the ſurface next the imaginary middle plane above-mentioned. Theſe arbitrary terms, though applicable only to one determined poſition of the body, are yet neceſſary to give tolerable preciſion to anatomical deſcription: when by their aſſiſtance we have made ourſelves familiar with the objects they are deſigned to illuſtrate, they may be diſmiſſed as eaſily as they have been adopted; our ideas of the relative ſituation of parts will be diſtinct, and may be applied readily to every poſſible variety of poſture. In order to obviate all ambiguity, we ſhall introduce alſo the nomenclature of Chauſſier, as conveying exact and preciſe notions of the relations of oppoſite bones to each other. The terms are generally ſimple, and always perſpicuous as applied to the preſent ſubject.

The upper extremity—is divided into four parts; the ſhoulder, the arm, the fore-arm, and the hand, each of which will be ſeparately conſidered.

The ſhoulder is the diviſion of the upper extremity attached immediately to the ſuperior and lateral parts of the trunk; it is formed by two bones, one broad, placed vertically behind, called the *ſcapula*, or ſhoulder blade, the other long, ſituated horizontally before, called the *clavicle*, or collar bone. The diſpoſition of theſe bones gives the broad form and character to the upper part of the cheſt, which is in itſelf very conſiderably contracted at this part, its apparent breadth and magnitude being derived from the lateral appoſition of the ſhoulders. Generally, alſo, there is a proportion between theſe and the dimenſions of the cheſt: they are large, and ſtrongly developed, when the latter is well formed; contracted and narrow when it is ſmall or badly ſhaped. The height of the ſhoulder depends on the ſituation of the ſcapula; it is lower proportionably in the female, and in males of a feeble body, than in individuals of the oppoſite character. In the latter caſe, though the bones form the outline, it is the brawny muſcles which fill it up, conſtituting, by their well-defined and maſſy forms, the diſtinguiſhing character of the ſex in man, and other animals.

The *ſcapula*, ſhoulder blade, or omo-plate, is a bone of an irregularly triangular figure, ſeated on the upper and back part of the trunk. It is connected by muſcles to the head, the vertebræ, and the ribs, by articulation to the clavicle and humerus. The ſcapula has ſuch a latitude of motion as to make it difficult to aſſign preciſely its ſituation on the trunk. But when the arm is at reſt, it covers the ſpace between the firſt and eighth ribs, with its baſe or poſterior margin at a ſmall diſtance from the vertebral column, to which it approaches nearer above than it does below. At this line the ſcapula lies pretty cloſe on the ribs; forwards, we find it receding conſiderably from the oppoſite ſurface of the trunk, in which ſituation it is conſtantly preſerved by its connection with the clavicle.

For convenience of deſcription, we divide the ſcapula into two ſurfaces, the dorſal or exterior, and the coſtal or interior; into three margins or coſtæ, the ſuperior, the poſterior, or baſe, and the inferior, or external coſta. The rounded points at which theſe edges meet are uſually called angles, and are named, from their ſeveral ſituations, the ſuperior, the inferior, and the anterior angles of the ſcapula.

The dorſal ſurface, the dorſum, or back of the ſcapula, is divided into two very unequal portions by a ſtrong and ſolid proceſs of bone projecting from it tranſverſely, called the ſpine of the ſcapula. It commences at the poſterior margin, about one-fourth part of the whole length below the ſuperior angle, increaſes gradually in depth as it advances obliquely forward towards the anterior angle, beyond which it projects in the form of a broad, flat proceſs, called the acromion. The ſpine is connected with the whole breadth of the dorſum, with the exception of that portion of it called the neck; its anterior edge is ſmooth, rounded, and concave, and is gradually loſt in the under ſurface of the arch of the acromion. The poſterior, or projecting ridge of the ſpine, is broad and flattened, varying however in breadth in different parts. At its commencement is a ſmooth, triangular ſpace, over which paſſes a part of the tendon of the trapezius. Further on it is rough, the upper margin of the criſta giving attachment to this muſcle, the lower to the poſterior half of the deltoid. The acromion is flattened in a direction contrary to that of the ſpine of which it is a continuation, is of conſiderable breadth, rough and ſomewhat convex above, concave and ſmooth below. On the internal edge, which is continuous with the ſuperior criſta of the ſpine, is a ſmooth oval ſurface for articulation with the clavicle. The external edge is rough and irregular, giving attachment to the middle part of the deltoid. The ſummit of the acromion is rounded, and marked by the attachment of a ligament which connects it with the coracoid proceſs. Towards the anterior part of the baſis of the ſpine, near the neck, we obſerve holes for the admiſſion of the nutrient veſſels. The upper ſurface of the ſpine is hollow, forming a portion of the ſupra-ſpinal foſſa, the name given to that portion of the dorſum ſituated above the ſpine, and which gives lodgment to the ſupra-ſpinatus muſcle. The lower ſurface is alſo concave, though irregularly ſo, and contributes to the formation of the infra-ſpinal foſſa, the part of the dorſum lying below the ſpine, which is occupied by the infra-ſpinatus muſcle; the latter portion ſcarcely deſerves the name of foſſa, being convex in its centre. Towards the inferior part of the dorſal ſurface is a ridge running in the direction of the inferior coſta, for nearly its whole length; it gives attachment to an aponeuroſis, which ſeparates the infra-ſpinatus from the teres major, and teres minor. Towards the inferior angle this ridge is met at a very acute angle by another, originating in the inferior coſta. The latter forms the line of diviſion between the two laſt mentioned muſcles, the upper and ſmaller part giving attachment to the teres minor, the lower and broader to the teres major.

The under or coſtal ſurface of the ſcapula is concave, marked by ſeveral converging ridges running from the baſe towards the anterior angle. They give attachment to the aponeurotic diviſions of the ſub-ſcapularis, its fleſhy bundles lying in the intervening ſhallow depreſſions. Towards the ſuperior and inferior angles we mark ſome projecting points, which give attachment to the ſerratus major anticus, as alſo more or leſs evidently a riſing line between, deſigned for the ſame purpoſe.

The ſuperior margin, or coſta of the ſcapula, is the ſhorteſt of the three borders. It is thin towards the ſuperior angle, becomes broader as we trace it forwards to its termination in a ſtrong curved proceſs, called, from its ſimilarity to a crow's beak, the coracoid proceſs. At the root of this proceſs we obſerve a deep notch, croſſed by a ligament, ſo as to form a circular hole; in many inſtances the circle is completed by bone. It gives paſſage to the ſupra-ſcapulary nerve, and uſually to a branch of the ſupra-ſcapulary artery and veins. Juſt behind this notch the omohyoideus muſcle has its origin. The coracoid proceſs is rather flattened, convex and rough above, where it gives attachment to ligaments connecting it with the under ſurface of the clavicle, concave and ſmooth below. Its internal edge gives attachment to the pectoralis minor, its external to a ſtrong ligament, croſſing from it to the acromion, its ſummit to the united heads of the biceps, and the coraco-brachialis.

The baſe of the ſcapula is the longeſt of the three margins, offering a waving line with an obtuſe projection in it, oppoſite the commencement of the ſpine; to this, and to the margin below it, the rhomboidei are attached. From its junction with the ſuperior coſta reſults the ſuperior angle, to which the levator ſcapulæ is partly attached.

The inferior coſta is much broader than the other, dividing at its anterior part into two projecting lines, with a hollow between them. Towards the inferior angle, where it joins the baſe, the edge is thinner, and convex, giving attachment to the teres major, and occaſionally to ſome fibres of the latiſſimus dorſi. The outer of the prominent lines gives origin above to the long head of the triceps; below to the teres minor. The inner line, and intervening hollow, is occupied by the ſub-ſcapularis. The inferior coſta terminates above, at the anterior angle, towards the coracoid proceſs, in an ovate, ſlightly hollowed ſurface, called the glenoid cavity. This ſurface is at right angles with the plane of the bone, its long diameter perpendicular, and its broader part below. It is covered by cartilage, the edges raiſed a little by a fibrous ring, which adds ſomewhat to its depth. At the upper end of the brim is attached the long head of the biceps. The glenoid cavity is articulated with the head of the humerus; it ſtands off a little from the body of the bone, ſupported by a ſhort proceſs, more contracted than the brim of the cavity, called the neck of the ſcapula. This narrowing is more particularly obſervable on the back, under the ſpine.

The ſcapula is, in its ſtructure, compact; thin and diaphanous every where but at its edges and proceſſes, where the bone is thick and cellular. Its oſſification commences at an early period in the fœtus, and advances conſiderably before birth. At the latter period, however, the acromion, the coracoid proceſs, and the baſe, ſtill exiſt in the ſtate of cartilaginous epiphyſes.

The clavicle, or collar bone, is placed nearly tranſverſely at the ſuperior and anterior part of the cheſt, between it and the top of the ſhoulder. In figure it ſomewhat reſembles the italic *ſ*; the two thirds next the ſternum being of an irregularly cylindrical, or nearly priſmatic form, and gently convex anteriorly; the third next the ſcapula flattened horizontally, broad, and with a more conſiderable convexity directed backwards. It is more ſlender, and leſs curved in the female than in the male.

The extremities of the bone are diſtinguiſhed from their ſituation by the names of the external or pectoral, and the ſcapular, or humeral ends of the clavicle. The firſt of theſe is triangular, preſents an irregular articular ſurface of conſiderable extent for connection with the ſternum; its plane is nearly at right angles to the body of the bone. The ſcapular extremity preſents alſo a flat, articular ſurface, oblong horizontally, accommodated to the oppoſite one in the acromion. The upper ſurface is rounded towards the ſternum, where the ſterno-cleidomaſtoideus is attached, ſmooth in its middle portion, flat and broader next the ſcapula. The under ſide, to which theſe characters are equally applicable, is marked near the ſternal end, by a roughened ſurface, for the attachment of a ligament connecting the clavicle to the firſt rib. Towards the middle is a conſiderable longitudinal hollow for the lodgment of the ſubclavius muſcle. Near the ſcapular end the face of the bone is unequal, with a rough eminence in it for the inſertion of ligaments which bind it to the coracoid proceſs of the ſcapula. Towards the ſternum the anterior edge is broad, and bends gently forwards, for about one-half of its length, where it gives origin to a portion of the pectoralis major; it then becomes thinner, ſlopes backwards, and terminates by ſuddenly turning forwards again towards its junction with the acromion. It gives attachment to the anterior half of the deltoid. The curvatures of the poſterior edge are the inverſe of the preceding. The bone is rounded, ſmooth and concave for the two-thirds next the ſternum; unequal and convex towards the ſcapula, where the trapezius is attached.

The clavicle is in ſtructure like the other long-bones; the medullary cavity is very confined. At the time of birth its form is already ſtrongly marked, and its oſſification nearly complete.

The articulations of the ſhoulder.—The ſcapula is connected with the trunk by a great number of muſcles, which partly ſupport it, and allow of all thoſe varied motions of which it is capable. It is cloſely bound alſo to the clavicle, which latter bone is immediately articulated with the ſternum. We have here only to examine the two laſt connections, beginning with that between the clavicle and ſternum, as forming the union between the ſhoulder and the trunk.

The ſternal end of the clavicle is covered by a cartilaginous cruſt of conſiderable thickneſs, preſenting an irregular convex ſurface. At the upper part of the ſternum is an articular cavity, ſlightly hollowed, of leſs extent than the oppoſite articular ſurface of the clavicle, ſo that the latter riſes conſiderably above it; a circumſtance particularly ſtriking in lean perſons.

The ligaments which connect theſe ſurfaces are four, an anterior and a poſterior, an inter-clavicular, and a coſto-clavicular ligament. To complete the joint, we find alſo an inter-articular cartilage, dividing it into two ſeparate cavities, and a diſtinct capſular membrane lining each of theſe.

The anterior ligament covers the front of the joint, lying between the ſkin and the ſterno-maſtoideus without, and the capſules immediately within. It is compoſed of fibres, which deſcend obliquely from the upper and anterior edge of the clavicle, diverging as they proceed to be fixed into the upper edge of the articular cavity in the ſternum. Theſe ligamentous fibres leave ſeveral intervals between them, which are occupied by cellular tiſſue and veſſels.

The poſterior ligament is ſmaller and not ſo ſtrong as the anterior. It ſeparates the ſterno-hyoideus and ſterno-thyroideus from the capſules to which it firmly adheres. It extends from the poſterior edge of the clavicle to the oppoſite part of the ſternum. The fibres deſcend a little in their paſſage, diverging as they approach the latter bone.

The inter-clavicular ligament is placed between the two clavicles, immediately above the hollow at the upper edge of the ſternum, with the integuments only in front, and the ſterno-hyoidei and ſterno-thyroidei behind. It is attached to the upper edge of the ſternal extremity of each clavicle, the fibres croſſing in a flattened form from one to the other, and longer above than below; they are often ſeparated by intervals filled up with cellular tiſſue.

The coſto-clavicular, or rhomboid ligament, paſſes obliquely upward from the cartilage of the firſt rib to the internal edge of the under ſurface of the clavicle, cloſe to its ſternal end. It is flat and ſhort, the fibres becoming longer as they recede from the ſternum. In front of it lies the ſubclavian muſcle, and immediately behind it the ſubclavian vein. It has no immediate connection with the articulation, but ſerves to ſtrengthen it and regulate its motions.

Between the clavicle and ſternum we find an intermediate round, flattened piece of fibro-cartilage, its ſurfaces accommodated to the ends of theſe two bones. Its circumference lying immediately under the ligaments of the joint, is united to the ſurface of the anterior and poſterior. It is united alſo above and below, by means of a ſtrong and thick fibrous ſubſtance, to the circumference of the articular ſurface of both the clavicle and ſternum. The fibro-cartilage is thicker above, and much thinner next the cartilage of the rib. The fibres which compoſe it are leſs apparent in its middle than nearer its edges. From its cloſe connection with the ſurrounding parts, it cannot be moved in any of the actions of this joint.

The capſular membranes adhere to the ligaments which ſurround the articulation, between the fibres of which they are often apparent. They both adhere alſo to the fibro-cartilage, one of them lining the cavity between it and the ſternum, the other the correſponding cavity between it and the end of the clavicle. The membrane is every where delicate, its inner ſurface moiſtened by ſynovia, which is ſecreted but in a very ſmall quantity.

From the diſpoſition of the ligaments belonging to this articulation, there remain but few intervals not covered and ſupported by them; ſo that it nearly approaches in ſtructure thoſe joints which we find ſurrounded by a fibrous capſule, as in the caſes of the ſhoulder and the hip, which it ſomewhat reſembles, alſo in the extent of its motions.

Articulation of the clavicle with the ſcapula.—At the ſcapular extremity of the clavicle we find a ſmall oval facet, covered by cartilage, correſponding to a ſimilar one in the internal edge of the acromion. We often meet alſo with a delicate inter-articular cartilage, its ſuperficies ſometimes equalling the articular ſurfaces of the bones, at others leſs; it is thickeſt above, and adheres by its circumference to the ligaments. To ſecure this joint, we find ligaments above and below it; and the clavicle is further bound to the coracoid proceſs of the ſcapula by ſtrong ligaments, without being any where in contact with it.

The upper ligament forms a broad and flat band, which covers the whole length of the articulation, croſſing from the upper edge of one articular ſurface to the other, the fibres being longer as they are ſeated more ſuperficially. It lies immediately under the tendinous aponeuroſes of the trapezius and deltoid, which form a ſtrong, diſtinct layer of fibres, not eaſily ſeparable from the ligament.

Underneath the joint lies another ligament, the fibres following the direction of the preceding, which it approaches in front, being ſeparated behind by an interval filled with cellular tiſſue. Above, it is in contact with the capſular membrane; below, with the ſupra-ſpinatus. The ſynovial membrane is found lining the articular ſurfaces, reflected from one to the other, and containing but little ſynovia. It is ſometimes double, where the inter-articular cartilage is perfect.

The ligaments which further connect the clavicle with the ſcapula are attached to the coracoid proceſs, from which they purſue different directions to be inſerted into the clavicle. The moſt delicate of theſe has been called the ligamentum bicorne. It ariſes from the inner edge of the coracoid proceſs, near its point, and, as it advances upwards and inwards, ſplits into two layers, which envelope the ſubclavian muſcle. The upper band is attached to the clavicle, near the end of the rhomboid ligament; the under layer paſſes to the rib immediately below it. It is not ſtrong enough to add much to the ſecurity of the connection between the bones. The other ligamentous bands, placed between the coracoid proceſs and the clavicle, have been divided by many authors into two diſtinct ligaments: one, the poſterior bundle, has been called, from its figure, conoides; the other, for a ſimilar reaſon, trapezoides. Though ſcarcely diſtinct in their origin, they differ ſo much in figure, and in the direction of their fibres, that we ſhall conſider them as ſeparate ligaments. The poſterior ligamentum ſcapulæ commune conoides is attached below, by the ſummit of the cone, to the root of the coracoid proceſs; above, to the rough tubercle ſituated on the under ſide of the humeral end of the clavicle. It is compoſed of ſhort thick fibres, radiating as they aſcend, parallel to, and continuous with thoſe of the anterior ligament, as they approach nearer the acromion. Below, its fibres are often united with thoſe forming the ligament croſſing the notch of the ſcapula. The anterior ligament, ligamentum commune trapezoides, croſſes obliquely from the coracoid proceſs to the clavicle, as a broad flattened band, exceeding the preceding in length. It is fixed below to the poſterior part of the upper ſurface of the coracoid proceſs, above, to an oblique line proceeding from the tubercle towards the end of the clavicle. The anterior fibres are longer than the poſterior; the latter, at the union with the fibres of the poſterior ligament, form an angle pointing towards the acromion, and leaving in front an angular cavity which is filled by fat. Theſe ligaments are covered by the ſubclavius in front, by the trapezius behind, leaving an interval of an inch or more towards the ſcapulo-clavicular articulation.

The ſcapula has two other ligaments proper to itſelf, which we ſhall deſcribe here, although they have no immediate relation with the articulation of the clavicle and ſcapula. One cloſes the notch in the laſt-named bone, the other is extended between the coracoid proceſs and the ſcapula. The firſt, conſiſting of a flat, compact band of ſilvery ſhining fibres, croſſes from the poſterior angle of the notch to the baſe of the coracoid proceſs, converting it into an hole, through which the ſupra ſcapulary nerve, and frequently alſo the ſupra ſcapulary veſſels paſs.

The ligament placed between the coracoid proceſs and the acromion is of a triangular form, of conſiderable ſurface, thin, and flattened. Its baſe is attached along the external edge of the coracoid proceſs, from which it proceeds in two diſtinct bands, ſeparated by cellular tiſſue, and converging, as they approach the acromion, into one common ſheet. The poſterior fibres paſs obliquely outwards, the anterior are directly tranſverſe; the interval between them is croſſed by ſome ſcattered ſlips of ligament. Its upper ſurface is covered by the deltoid and clavicle, its lower ſide is in contact with the ſupra-ſpinatus. Its anterior edge is not defined, but continuous with a thick and denſe layer of cellular membrane, lying between the deltoid and the tendons of the infra and ſupra-ſpinatus. This ligament completes the arch formed by the coracoid proceſs and acromion over the ſhoulder-joint.

The mechaniſm and motions of the ſhoulder.—The ſcapula, by its muſcular connection with the trunk, is capable of powerful and varied motion; the clavicle, on the contrary, can only follow the impulſe communicated by the ſcapula, whoſe motions it regulates and limits under certain circumſtances. The ſcapula forms the eſſential part of the ſhoulder, the clavicle can be conſidered only as acceſſory in man, and ſome animals who uſe their anterior extremities for other purpoſes beſides progreſſion. The ſcapula may in ſome meaſure be conſidered as defending that part of the thorax over which it moves; but its more evident uſe is to ſerve as the baſe of all the motions of the arm, which at the ſame time it increaſes moſt extenſively. In this reſpect it differs from the hip, which is in itſelf motionleſs, although affording a point from which the thigh directs all its movements. We ſhall recur to this difference hereafter: in this place it will be ſufficient to notice, that notwithſtanding the apparent want of firmneſs in the ſhoulder, it is enabled, by means of its numerous and powerful muſcles, to offer a ſolid reſiſtance to the impulſe communicated from the arm in any of the violent actions of the upper extremity. The ſcapula plainly accompanies the motions of the arm, forwards and backwards, but in the ſimple elevation outwards, and in depreſſion of that bone, its movement is ſcarcely obſervable. In the former caſes it rotates on an imaginary axis, perpendicular to its plane, placed ſomewhat about the middle of the bone.

In the inſtance where the arm paſſes forward from the ſtate of adduction, the ſuperior angle of the ſcapula is lowered a little, and approaches the vertebral column, whilſt the inferior recedes from it, and is at the ſame time ſomewhat elevated. Where the arm is carried backwards the converſe of this occurs. In theſe rolling motions the clavicle is concerned but little if at all; the ſcapula turning on it at the joint which unites them, the articular ſurfaces gliding on each other, and the ligaments above and below becoming alternately ſtretched or relaxed, as the motions are ſucceſſively continued. They, however, are not capable of reſiſting alone any violent effort tending to diſplace the bones in this rotatory motion; it is the ſtrong ligaments croſſing from the coracoid proceſs to the tubercle of the clavicle which, by their alternate tenſion, ſecure their relations under theſe circumſtances. This articulation is further defended from injury by the mobility of both bones, which would recede before any violent ſhock.

The clavicle acts as a prop, preventing the ſhoulder and arm from falling forwards and approaching the breaſt, either by their weight or by the action of the muſcles which move them. It is partly preſerved in its ſituation by muſcles which are fixed to it above. Its exiſtence is neceſſary for many of the motions of the upper extremity, particularly thoſe in which it is carried forward; it favours alſo the circumduction of the arm, by keeping it at a diſtance from the trunk, and allows the whole limb to deſcribe arcs of a ſphere, the centre of which is found at its ſternal end. We find conſequently that animals without clavicles enjoy theſe motions but imperfectly, in many inſtances in no degree. Their abolition in the caſe of fractured clavicle is another proof of the utility of the latter in directing the actions of the ſhoulder.

The combined motions of the ſcapula and clavicle are thoſe of depreſſion, elevation, thoſe in which the ſhoulder is carried forward, or backward, and the combination of theſe or circumduction.

When we raiſe the ſhoulder, the ſcapula paſſes during its elevation a little obliquely forward. The inferior angle advances, whilſt the upper edge or coſta recedes from the trunk. The ſcapular end of the clavicle is neceſſarily alſo raiſed, ſo as to increaſe the ſpace between it and the firſt rib, and to diminiſh ſomewhat the angle it forms with the acromion, its ſternal end preſſing more and more on the articular cavity in the ſternum; the rhomboid ligament is ſtretched, limiting the elevation, and the inter-clavicular ligament relaxed.

In depreſſing the ſhoulder the exact inverſe of theſe effects is produced, and requires not therefore a minute detail. We ſhall obſerve only that the lower ſurface of the clavicle may be brought ſo near to the firſt rib, as to compreſs the intervening veſſels very conſiderably, and produce a painful ſwelling of the arm. The depreſſion is much limited by this contiguity of the rib, which lies pretty cloſe to the clavicle in the moſt common and eaſy poſition of the ſhoulder.

When the ſcapula advances forwards its anterior angle recedes from the trunk, being kept off by the clavicle, the baſe at the ſame time approaching nearer the breaſt. The clavicle becomes more diſtant from the firſt rib in the horizontal direction, the inter-clavicular, and the poſterior ligaments are rendered tenſe, the ſternal end preſſing inwards and backwards. In this ſituation luxations have occurred, but the accident is rare, as the ſhoulder is ſeldom expoſed to any violence under theſe circumſtances, that by its direction would probably effect it.

In carrying the ſhoulder backward, the anterior angle of the ſcapula is brought nearer to the cheſt, and the baſe approaches the ſpine. As the ſcapula has a conſiderable extent of motion in this direction, and is accompanied by the ſcapular end of the clavicle, it will readily be conceived, that if the movement is ſudden and violent, the ſternal end will diſtend its anterior ligament, may rupture it and become luxated forwards on the ſternum. In fact this is the moſt common mode of diſplacement.

The ſhoulder may be moved in any of the intermediate directions to thoſe we have deſcribed; and in all we are to conſider it as a lever compoſed of two parts, one horizontal, the other vertical, the ſternal end of the clavicle being the reſting point, or the centre of the movements of the lever. The continued ſucceſſion of all theſe motions produces the circumduction of the ſhoulder, a motion in which the clavicle deſcribes a cone, the ſummit of which will be at its ſternal, and the baſe traced by its ſcapular extremity. We are not to confound this motion of the ſhoulder with that of rotation, deſcribed above.

The direction of the ſhoulder is ſubject to variations from the ſlighteſt motion; in general it is ſo inclined that the glenoid cavity points outwards, proving moſt evidently, if any argument were wanting, that the upper extremities are not deſigned to ſupport the body in the attitude of a quadruped. In fact, in that poſition, the head of the arm bone would preſs, not againſt the glenoid cavity, but on the capſular ligament which ſurrounds it, and which is utterly incapable of long reſiſting the effort.

The Arm.—The humerus, the only bone in the arm, the largeſt and ſtrongeſt of thoſe of the upper extremity, is placed between the ſhoulder and the fore-arm. It is nearly ſtraight, bending gently forwards below, "tanquam ad meliorem amplexem," ſays Albinus. Of an irregular priſmatic form, ſomewhat rounded at its upper and middle portions, flattened and gradually widening below, ſo as to be broadeſt at its lower end where it ſupports the fore-arm. It has the appearance of having been twiſted in the middle, as if at an early period the upper end had been carried round forcibly outwards, and the lower end in the oppoſite direction. We divide it into two extremities, a ſuperior or ſcapular, and an inferior, or cubital; and into a middle portion or body.

At the upper end, the moſt bulky part of the bone, are three eminences; the head, and the great and ſmall tubercle of the humerus. The head of the humerus is rounded, forming nearly the half of a ſphere, ſmooth, covered by cartilage, articulated with the glenoid cavity of the ſcapula. It ſtands on a very ſhort proceſs, ſomewhat more contracted than the articular circumference, called improperly, perhaps, the neck of the humerus. The head and neck are directed obliquely upwards, ſo that a line drawn in their axes would form an obtuſe angle with the body of the bone; they are alſo inclined backwards with reſpect to the plane of the condyles at the lower extremity. From this oblique poſition of the head with regard to the body of the humerus, the neck is longer, and the contraction more ſtrongly marked below than it is above, where we remark only a ſhallow groove dividing the head from the tubercles.

The great tubercle is placed externally, oppoſite to the head. It is rough, broad, and flattened; marked by three diſtinct ſurfaces for the attachment of tendons. One, anterior, for the tendon of the ſupra-ſpinatus muſcle; a middle ſpot, for that of the infra-ſpinatus, and one below for the teres minor. The leſſer tubercle, placed in front of the bone, is rough, much ſmaller but more elevated than the laſt. It gives attachment to the ſub-ſcapularis. Dividing the tubercles is a deep longitudinal groove, of which we ſhall ſpeak below.

The body of the humerus, though of a very irregular form, is ſufficiently marked for us to divide it into three differently inclined ſurfaces, and as many projecting lines between them. Owing to the twiſted figure of the bone theſe angular lines purſue rather a ſpiral than a ſtraight courſe.

The anterior ridge or ſpine commences at the inner edge of the great tubercle, and is continued through the middle of the bone to the lower end. It is rough in its upper half, giving attachment above to the pectoralis major, and lower down to a portion of the deltoid: below it is rounded and ſmooth, giving attachment to and covered by the brachialis internus. The internal line deſcending from the ſmall tubercle, gives attachment above to the latiſſimus dorſi, and lower down to the coraco-brachialis and triceps. Towards the anti-brachial extremity it becomes much more prominent, affording attachment to a ſtrong inter-muſcular aponeuroſis. The external edge begins at the under ſide of the neck, running obliquely forwards as it deſcends. It is but faintly marked above where it gives attachment to a portion of the triceps; is interrupted towards the middle, leaving a ſmooth flat ſurface, over which the radial nerve and accompanying veſſels turn; below it riſes again into a more acute, and elevated ridge, which gives attachment to an inter-muſcular ligament, and ſome muſcles belonging to the fore-arm. In the internal ſurface, bounded by the anterior and inner lines, we obſerve above the bicipital groove, continued between the tubercles and the ſpines, proceeding from them for ſome way down the bone, increaſing in breadth, and gradually becoming obliterated. It is lined by cartilage, and provided with a ſynovial membrane, where it lodges the tendon of the long head of the biceps. Towards the lower end of the groove, at its outer ſide, is a rough line for the inſertion of the tendon of the teres major. About the middle of the internal ſurface the coraco-brachialis has an attachment, and below this the brachialis internus. The external face is larger than the preceding: covered above by the deltoid, ſtrongly marked by a rough prominence interſecting it obliquely for the inſertion of this muſcle. Immediately below this ridge is a broad ſhallow oblique depreſſion, along which the radial nerve and ſome veſſels paſs. Towards the lower extremity the bone is ſlightly concave, and gives attachment to the brachialis internus. The poſterior ſurface is ſmooth and rounded, altering its direction in a conſiderable degree as we trace it downwards: it gives origin to and is covered by the triceps.

The lower, or anti-brachial extremity of the humerus, is broad and flattened tranſverſely, and advances a little forwards from the axis of the body of bone. In the middle is an articular ſurface for connection with the fore-arm, and on either ſide a projecting point, called tuberoſity, or condyle. Of theſe the internal (poſterior of Albinus) is the moſt projecting. It is ſomewhat flattened, continuous above with the internal ſpine, marked irregularly below by the attachments of muſcles, and the internal lateral ligament of the elbow joint. The external condyle (prior Albini) is much leſs prominent, and gives attachment to the external lateral ligament, as well as to ſeveral muſcles which lie on the radial and dorſal ſides of the fore-arm.

The articular ſurface, placed between theſe two points, deſcends a little way beyond them. It is marked by ſeveral eminences and hollows. Next to the external condyle is a rounded eminence (capitulum of Albinus) adapted to the hollow in the head of the radius, and at its inner ſide is a groove for the internal projecting edge of that hollow. The remaining diviſion forms the pulley or trochlea (rotula of Albinus) for articulation with the ulna. We obſerve two prominent edges and a depreſſion between them. The edge next the radius is not ſo prominent in front as behind, neither does it riſe ſo high as the edge next the internal condyle, which deſcends a conſiderable way below the reſt of the articular ſurface, ſloping gradually into the hollow of the pulley on one ſide, and terminating abruptly by an acute margin on the other. The hollowed part, forming nearly three-fourths of a circle in extent from before backwards, is much broader behind, directed from thence obliquely inwards as we follow it to the front of the bone. Above the middle of the pulley, at its back part, is a deep cavity, oblong tranſverſely, which receives the olecranon, or extremity of the ulna, during the extenſion of the fore-arm. Oppoſite to this, at the termination of the pulley in front, is a ſmaller hollow for the reception of the coronoid proceſs of the ulna, when the fore-arm is bent. Between theſe correſponding hollows there remains but a thin plate of bone, in many inſtances diaphanous.

The humerus reſembles in ſtructure the other long bones. Its oſſification commences at three points; at the middle and at each end. At the time of birth the ſcapular extremity of the humerus is entirely cartilaginous, and of greater proportionate bulk. At the lower extremity the capitulum is much larger in compariſon with the trochlea than in the adult bone.

The articulation of the humerus with the ſcapula, forming the ſhoulder joint.—The head of the humerus is covered by a layer of cartilage, much thicker in the middle than at the circumference. The glenoid cavity of the ſcapula is lined by cartilage, thinner in the middle than round its edges. The margin of the cavity is further provided with a fibrous elevated border, proceeding above from the tendon of biceps which gives off a bundle on either ſide; below, from the circumference of the articular cavity. Over the joint is the bridge formed by the acromion, the coracoid proceſs, and the ligament ſtretched acroſs between them. The head of the humerus moves on the glenoid cavity; but from the ſmall relative ſize of the latter, the ſurface of the head of the humerus in contact with it forms but a ſmall part of its articular ſuperficies, the remainder of which is thus out of the cavity, and correſponds to the capſular ligament.

The capſular or orbicular ligament encloſes the whole of the joint in the form of an oblong ſac, contracting a little at each extremity. The upper edge is fixed round the glenoid cavity of the ſcapula, beyond the fibrous ring we have juſt mentioned. In ſome inſtances there is an interval left on the inner ſide, which is then ſupplied by the tendon of the ſub-ſcapularis. The lower edge is attached round the neck of the humerus; cloſe to the margin of the articular cartilage above, at a greater diſtance from it below. The attachment is interrupted between the two tubercles, the ligament croſſing from one to the other over the bicipital groove. The deficiency occaſionally obſerved on the inner ſide is ſupplied as above by the tendon of the ſub-ſcapularis, which may be ſeen from within the joint covered only by the reflected ſynovial membrane. The capſular ligament is remarkable for its length, which allows the articular ſurfaces of the two bones to be ſeparated from each other, by the diſtance of an inch, on the admiſſion of air into the cavity. It is covered above by a denſe ligamentous band paſſing from the outer edge of the coracoid proceſs, to the anterior part of the larger tubercle, where it unites with the tendon of the ſupra-ſpinatus; and ſo cloſely joined by its under ſurface to the capſular ligament, that, but for its attachment to the coracoid proceſs, it would be difficult to make any diſtinction between them. It is this acceſſary band which makes the capſular ligament thicker above than in any other part. The ſhoulder joint is further ſtrengthened by the tendons of the ſupra-ſpinatus, infra-ſpinatus, teres minor, and ſub-ſcapularis, which ſurround it, and which are firmly united to different parts of the capſular ligament. The latter is in contact alſo with the deltoid above, and the origin of the long head of the triceps below. It is formed by fibres running in various directions, and croſſing each other, is thinneſt where covered by the infra-ſpinatus, and teres minor, ſtronger on the inner and under ſides; apparently inſufficient to ſecure the firmneſs of the articulation, if not ſupported by the muſcles proceeding from the ſcapula. The ſynovial membrane is ſpread over its internal ſurface, and reflected over the articular cartilages. At the edge of the bicipital groove a proceſs goes from it, which deſcends along the groove, lining it for the ſpace of about an inch. It is then reflected on all ſides over the tendon of the long head of the biceps, and continues to give it a covering in its paſſage through the joint to its attachment above the glenoid cavity. By the reflection of the ſheath below, the eſcape of ſynovia is prevented, and the tendon may ſtill be ſaid to be exterior to the cavity of the joint.

The mechaniſm of the ſhoulder joint as to mobility and reſiſtance.—Although motion be the principal office of the upper extremity, there are many accidental circumſtances in which firmneſs of oppoſition is as neceſſary as in the lower, and the means nearly as complete.

The motions of the arm are very extenſive, generally combined in different degrees with thoſe of the ſhoulder. Indeed ſo great is its mobility, that it eſcapes on that account many injuries it would otherwiſe be liable to, from the looſeneſs of its articulation with the ſhoulder. Add to this that the point of ſupport, the glenoid cavity of the ſcapula, is in itſelf ſo moveable, as further to modify and leſſen the effects of external impulſes. We have before obſerved that the ſcapula more particularly accompanies the arm in its motions backwards and forwards, leſs ſo in its elevation outward and depreſſion; the clavicle neceſſarily partakes of the movement, and from this diſpoſition two advantages are derived that the circuit of motion is enlarged, whilſt tendency to diſplacement is diminiſhed by the diſtribution of the effort over three points inſtead of one.

The arm, and conſequently the whole limb, may be elevated, depreſſed, carried forward, backward, and in all the intermediate directions; it may be rolled alſo on its axis in any of theſe conditions.

When the arm is raiſed, the head of the humerus glides from above downwards in the glenoid cavity, in ſome meaſure abandons it, and reſts againſt the lower ſide of the capſular ligament, which it diſtends more or leſs according as the ſcapula has accompanied it in its movement. If the arm be elevated outwards or abducted, it cannot be much aſſiſted by the ſcapula; the great tubercle is buried under the arch formed by the acromion, the coracoid proceſs, and the ligament between them, and in this ſituation the capſule is particularly ſtretched, is liable to be torn, and the arm luxated downwards. When the arm is thus raiſed above the horizontal line, at a diſtance from the trunk, the weight of the body brought to bear with force on the head of the bone, as in the caſe of falling, tends to depreſs it ; and at the ſame time the actions of the pectoralis major, latiſſimus dorſi, and teres major, concur in producing the ſame effect ; ſince they have their fixed points in the trunk, and their moveable point in the humerus. Luxation, under theſe circumſtances, is by no means rare. The action of muſcles alone is ſcarcely adequate to the effect, which is generally the conſequence of ſome violent impulſe.

In depreſſion or adduction, the arm returns to its natural poſition, in which diſplacement is almoſt impoſſible. Where the limb is perpendicular, any external impulſe acting on its lower end, would only preſs the head of the bone firmly againſt the arch of the acromion. The only mode in which it could be made to paſs beyond the arch, would be by carrying the lower end inwards ; but this is oppoſed by the trunk, ſo that in this poſition of the arm luxation upwards is effectually prevented.

When the arm is carried forward to a conſiderable height, it is accompanied in its motion by the rotation of the ſcapula, and the head of the bone ſcarcely quits the glenoid cavity. It is on theſe accounts that when in falling forward the arm is projected conſiderably beyond the head, luxation is rarely the conſequence, though the ſhock be ſevere. In the motion backwards the head of the humerus quits in ſome degree the articular cavity, and bears againſt the capſular ligament and the tendon of the ſub-ſcapularis. The extent of this motion is alſo increaſed by the coincident movement of the ſcapula, and at the ſame time the probability of luxation diminiſhed ; it is not, however, ſo free as the motion forwards.

Circumduction, or the ſucceſſion of theſe motions, is enjoyed extenſively in the joint of the ſhoulder ; the execution of it in the anterior half of the circle is more eaſy, becauſe more unconfined than in the poſterior. And we may obſerve as a general axiom, applicable to all the motions of the arm, that the movements forwards are far more extenſive than thoſe in the contrary directions, whatever be the point from which they commence, in whatever direction the limb may be ; examples of theſe are too familiar for us to particularize them, the cauſe will be readily underſtood from our account of the mechaniſm of this part of the upper extremity.

The rotation of the arm takes place excluſively in the ſhoulder joint, not accompanied as the others by any correſponding motion of the ſcapula and clavicle. In this motion the head of the humerus merely glides backwards or forwards in the glenoid cavity, according as it is rolled inwards or outwards ; it is not extenſive, and cannot give occaſion to diſplacement of the bones. In caſes where the functions of the elbow joint have been ſo far deſtroyed, as to prevent the rolling of the bones of the fore-arm one over the other, the rotation of the humerus has been obſerved to be more marked, to compenſate the deficiency.

The fore arm, placed between the arm and the hand, is compoſed of two bones, the ulna and radius.

The ulna, the largeſt of the two, is on the inner ſide. Irregular in ſhape, ſtrong, and larger above, leſſening gradually in ſize to its lower end. We divide it into two extremities, an upper or humeral, a lower or carpal ; and into a middle portion or body.

The humeral extremity compriſes two ſtrongly marked eminences, the olecranon and coronoid proceſſes, and two lunated cavities, the largeſt articulated with the pulley in the lower end of the humerus, the leſſer with the head of the radius. The olecranon projects beyond the coronoid proceſs in a line with the body of the bone ; it is ſtrong, ſomewhat curved, rough above, where it affords attachment to the triceps ; ſmooth behind, where it lies immediately under the ſkin ; concave before, where it forms the upper part of the great ſigmoid cavity. The coronoid proceſs ſtands oppoſite to the olecranon in front of the bone. Its upper ſurface forms the lower part of the laſt named cavity, the under is marked by the attachment of the brachiæus internus. The edge next the radius is hollowed by the leſſer ſigmoid cavity, the oppoſite margin is acute, and gives attachment to the pronator teres, the flexor ſublimis, and the internal lateral ligament of the elbow joint. The great ſigmoid cavity (ſinus lunatus of Albinus) lies between theſe proceſſes. It is deeply concave longitudinally, adapted to the figure of the trochlea of the humerus ; divided tranſverſely in the middle by a contraction of the articular ſurface, and a faintly marked line between the narrowed points. The upper diviſion made by the olecranon is the largeſt. The cavity is divided alſo into two unequal portions, by a convex line traverſing its whole length, the internal diviſion is the largeſt, and moſt hollowed, for the reception of the inner border of the trochlea. The leſſer ſigmoid cavity is oval tranſverſely, ſlightly hollow, continuous above with the larger cavity.

The body of the ulna is of an irregular priſmatic form, largeſt above, curved gently forward, and turning towards the radius below. We diſtinguiſh in it three ſurfaces, and a like number of angular ridges between them. The anterior edge or ſpine paſſes from the leſſer ſigmoid cavity in a curved line to the carpal extremity ; it is acute above, and gradually ſoftened below, till it becomes ſcarcely viſible. It gives attachment to the interoſſeous ligament. The internal edge (poſterior, Alb.) is rounded, giving attachment to the flexor profundus above, to the pronator quadratus below. It follows a curved line from the inſide of the coronoid proceſs, and is ſomewhat more prominent below, for the attachment of the latter muſcle. The poſterior edge (exterior, Alb.) beginning from behind the olecranon, is ſtrongly marked in its upper two thirds, and inſenſibly loſt below. It gives attachment to an aponeuroſis. The anterior ſurface (latus interius, Alb.) is broader above than below, gibbous in the middle, and concave at each end ; the hollow part below is occupied by the pronator quadratus, the remainder gives attachment to flexor profundus. Towards the upper end is a ſmall hole directed upwards for the admiſſion of the nutrient veſſels. The poſterior ſurface (prius, Alb.) is divided through its whole length by a prominent line ; at the upper end of the internal diviſion is a triangular ſpace for the attachment of the anconæus ; below it is covered by the extenſor carpi ulnaris. The external diviſion, that neareſt the radius, gives attachment above to the ſupinator brevis, below to the extenſors of the thumb and fore-finger. The internal ſurface is broad, and a little concave above, giving attachment to the flexor profundus, convex and much narrower below, lying immediately under the ſkin.

The carpal extremity is ſmall, marked by two eminences ; one placed externally, called the head or capitulum, the other, from its ſhape, the ſtyloid proceſs. The head preſents a rounded articular ſurface, correſponding below to a triangular inter-articular cartilage placed between it and the carpus ; externally to an articular cavity in the inner ſide of the carpal extremity of the radius. The ſtyloid proceſs projects beyond the head ; it is ſmall, of a conical ſhape, the point giving attachment to the internal lateral ligament of the wriſt. Between theſe proceſſes is a tranſverſe groove, which gives attachment to the fibro-cartilage juſt mentioned. Behind they are ſeparated by another longitudinal groove, which lodges the tendon of the extenſor carpi ulnaris.

The ulna is formed from three points of oſſification, as the other long bones. At the time of birth the form of the olecranon is fully determined, whilſt the coronoid proceſs projects but little. The conſequence is, that the great ſigmoid cavity is leſs concave in compariſon than in the adult, and the leſſer ſigmoid cavity is proportionably ſmall and ſhallow.

The radius is ſituated on the outer ſide of the fore-arm. It is ſhorter than the ulna; ſmaller above than below, and gently curved in the middle. The upper or humeral extremity, called alſo the head of the radius, preſents a circular articular ſurface; ſlightly hollowed in the middle, correſponding to the rounded eminence on the cubital end of the humerus. The ſmooth articular ſurface is continued a ſhort way down the bone, and is broadeſt on the inſide, where it lies in the leſſer ſigmoid cavity. This diviſion is ſupported by a narrower portion of bone, cylindrical, and of an inch in length, called the neck of the radius. Immediately below, on the inner ſide, is an oval protuberance, ſmooth on its anterior half, over which the tendon of the biceps paſſes, ſeparated from it by a burſa mucoſa; rough poſteriorly where this tendon is inſerted.

The body of the radius is of an irregular priſmatic form, which makes a natural diviſion of it into three faces, and as many angular lines. The anterior edge is more prominent above than below. The upper part gives attachment to the long flexor of the thumb, to the flexor ſublimis, and to the ſupinator brevis; its lower to the pronator quadratus. The internal edge or ſpine, acute in the middle, rounded at each end, gives attachment to the interoſſeous ligament. The poſterior, prominent alſo in the middle, and diſappearing inſenſibly above and below, gives no muſcular attachments. The anterior ſurface is concave above, where it gives origin to the flexor longus pollicis; a little convex below, where the pronator quadratus is fixed. About its middle is the hole for the nutrient veſſels of the bone. The poſterior ſurface, like the former, increaſes gradually in breadth from above downwards, is irregular, gives attachment above to the ſupinator brevis, and lower down to the extenſors of the thumb; its inferior part, covered by the extenſor communis, the extenſor tertii internodii pollicis, and the indicator. The external ſurface is convex throughout. Its upper third gives attachment to the ſupinator brevis: about its middle is a rough eminence, into which the pronator teres is implanted; below it is covered by the radial extenſors of the carpus.

The carpal extremity is larger than the ſuperior, irregularly quadrilateral, the longeſt ſide anterior. We obſerve in it an articular cavity, oblique, ſlightly hollowed, croſſed by a riſing line from before backwards, adapted to two of the bones of the carpus; the outer diviſion to the os ſcaphoides, the internal to the ſemi-lunare. The anterior edge of the cavity is rough for the inſertion of ligaments. The poſterior offers two grooves; the internal, broad and ſuperficial, gives paſſage to the extenſor communis and indicator, the outer, narrow and deeper, follows an oblique courſe from within outwards and downwards: through it paſſes the extenſor tertii internodii pollicis. On the inner margin is a lunated articular ſurface, correſponding to the capitulum of the ulna. The outer ſide, divided from the poſterior by a riſing ſpine, is marked in a ſimilar manner by two hollows. The anterior offers two grooves for the extenſores primi and ſecundi internodii pollicis; the poſterior is marked by the tendons of the radial extenſors. At the ſharp ridge, between this ſide and the anterior, the ſupinator longus is implanted. The prominence between the hollows is continued downwards into a blunt proceſs, paſſing beyond the articular ſurface, called the ſtyloid proceſs of the radius. It gives attachment to the external lateral ligament of the wriſt. The radius reſembles, both in its formation and ſtructure, the other long bones. At the time of birth its extremities are yet cartilaginous; the lower end is ſooneſt completely oſſified.

The elbow joint; the articulation of the ulna and radius with the humerus.—The lower end of the humerus preſents an articular ſurface compoſed of alternate eminences and depreſſions, covered by a continued cruſt of ſmooth cartilage. The great ſigmoid cavity of the ulna is lined by cartilage, interrupted in the middle by a tranſverſe contraction and groove; continued into the leſſer ſigmoid cavity. The head of the radius is alſo covered by cartilage, continued over its circular margin for a ſhort way down its cylinder. The humeral end of the ulna correſponds to the pulley, that of the radius to the capitulum at the lower extremity of the humerus. Theſe ſurfaces are bound together by ligaments, and covered by a ſynovial membrane reflected from one to another.

The ligaments which more particularly ſecure the joint are called lateral, one being placed on its outer, the other on its inner ſide. The internal lateral ligament is fixed above to the internal condyle of the humerus. It radiates as it deſcends, dividing into two portions; the anterior is fixed to the inner ſide of the coronoid proceſs of the ulna, the poſterior, the ſmalleſt of the two, to the olecranon. The anterior diviſion is covered by the tendon common to the muſcles proceeding from the internal condyle, and is partially united to it. Immediately under the ligament is the capſular membrane. The external lateral ligament can with difficulty be diſtinguiſhed from the common tendon of the muſcles attached to the external condyle. It is fixed above to this condyle, below it is united to a large portion of the circle of the annular ligament of the radius. It is not ſo ſtrong, ſo large, nor ſo clearly defined as the internal lateral ligament, its fibres diverge conſiderably, and are in contact with the ſynovial membrane. In addition to theſe ligaments we find ſcattered bands of fibres traverſing in different directions, both before and behind the articulation; their irregularity ſcarcely admits of deſcription. Between them and the ſynovial membrane lie ſome cellular tiſſue and fat. This ſynovial membrane is reflected from the humerus cloſe at the margin of the articular cartilage, and is continued under the ligaments to the oppoſite ſurfaces of the ulna and radius, lining the ſigmoid cavities of the firſt, and ſpread over the head of the latter. It is common therefore to the articulations of the fore-arm with the arm, and of the bones of the fore-arm between themſelves. This joint is ſtrengthened alſo in a remarkable degree by the numerous muſcles which are attached round it, and which cover it on every ſide.

The motions of the fore-arm on the arm—are confined to flexion and extenſion, the ulna executing the principal part, the radius neceſſarily following the ſame direction. In a ſtate of complete flexion the coronoid proceſs of the ulna and the prominent margin of the head of the radius are found correſponding to the oppoſite hollows in front of the humerus, the olecranon below the condyles, having moved a conſiderable diſtance from the internal one. At this time the lateral ligaments are relaxed; the poſterior half of the trochlea of the humerus in contact with the capſular membrane, reflected from it to the olecranon, and protected by the triceps. Under theſe relations the joint is ſecure; diſplacement in any direction would be almoſt impoſſible, without ſome fracture of bone. In the intermediate ſtates between flexion and extenſion the articulation has not the ſame appearance of ſecurity; but from the great mobility of the lower end of the humerus; from its receding eaſily before every ſhock when the fore-arm is in ſuch ſituation, we ſeldom meet with a diſlocation of the latter under theſe circumſtances. In the extenſion of the fore-arm on the arm, the radius and ulna glide backwards over the articular ſurface of the humerus, until ſtopped by the olecranon becoming locked in the cavity adapted for its reception in the latter bone. At this time the lateral ligaments are tightened as well as the capſule in front of the joint. It is in the ſtate of complete extenſion that luxations moſt uſually occur, the humerus paſſing down in front of the bones of the fore-arm. This frequently happens in a violent fall on the hands. The whole weight of the body is carried forwards with conſiderable impetus on the arms which are ſtretched out to ſave the head from coming to the ground. In this caſe the fore-arm is fixed, and the humerus, following the impulſe of the body, ruptures the ligaments, and is thruſt forwards, the olecranon oppoſing itſelf to all diſplacement backwards. It would appear alſo, that a diſlocation might occur from lifting a heavy weight with the arm fully extended; but here the effort is voluntary, and the pain felt in the bend of the elbow is a ſufficient warning to deſiſt. When the fore-arm is extended it forms an obtuſe angle with the arm, and when bent it is not found in the ſame line with the humerus, but ſlants a little inwards towards the breaſt. Both theſe circumſtances depend on the obliquity of the pulley at the lower end of the humerus. This direction of the fore-arm, and conſequently of the hand in the ſtate of flexion, is particularly obſervable in man, and neceſſarily requires the exiſtence of a clavicle, without which the fore-arm, when bent, would be carried to the oppoſite ſhoulder. Thus in the different ranks of animals the exiſtence of a clavicle, and the motion of pronation, are found generally connected with this obliquity in the flexion of the fore-arm. In the ſtate of demi-flexion we may obſerve a ſlight lateral motion of the fore-arm on the arm, which cannot take place in the ſtates either of complete flexion, or extenſion.

The articulations of the radius with the ulna.—Theſe bones are in immediate contact at their humeral and carpal extremities; between theſe points there is a vacancy occupied by a flat interoſſeous ligament. Above, the head of the radius is received into the leſſer ſigmoid cavity of the ulna; below, it offers a ſhallow articular ſurface, which revolves on the capitulum at the carpal end of that bone. Firſt we ſhall examine the articulation at the humeral ends. It is lined by the ſynovial membrane common to it, and to the articulation of the fore-arm with the arm, and ſecured by a ſtrong flat circular band of fibres, called the annular or orbicular ligament of the radius. This ligament forms three-fourths of a circle, which is completed by the leſſer ſigmoid cavity, and in which the head of the radius turns. It is about three lines in breadth, fixed before and behind to the ends of the leſſer ſigmoid cavity, loſt inſenſibly above over the ſurface of the ſynovial capſule, to which it is firmly united, terminating by a more defined edge below. It is compoſed of parallel circular fibres, into which the external lateral ligament is fixed from above, as alſo ſome oblique fibres proceeding from the olecranon, the ligamentum adceſſorium poſticum of Weitbrecht. The annular ligament is of a denſe compact texture, frequently cartilaginous in advanced age. It lies immediately over the ſynovial membrane, but is no where connected in any degree with the radius. It is covered by muſcles.

The ſpace between the upper and lower articulations is filled by the intervention of ligamentous fibres, which further ſecure the relations between the radius and ulna. A portion of theſe has obtained the name of the oblique ligament, or chorda tranſverſalis; the remainder is included under the general term of interoſſeous ligament. The oblique ligament, a ſmall and flat band of fibres, paſſes obliquely from the inner edge of the coronoid proceſs below the leſſer ſigmoid cavity to be inſerted into the radius at a point which lies juſt below its tubercle. In this courſe it accompanies the inner edge of the tendon of the biceps, its direction being oppoſite to the fibres of the interoſſeous ligament, and in a plane anterior to them. Between this ligament and the head of the radius there is left a triangular ſpace filled by cellular tiſſue, in which the tubercle of that bone revolves. The interoſſeous ligament commences below the tubercle attached to the inner ridge or ſpine of the radius, from which the fibres paſs obliquely downwards and inwards to be attached to the oppoſite ſpine of the ulna. It is compoſed of flat parallel fibres, leaving various intervals for the paſſage of veſſels. It is covered on both its ſurfaces by the deep ſeated muſcles of the fore-arm, to which it affords attachments. It is more delicate above, inſenſibly loſing its ſhining appearance, and interrupted by a large vacancy, which gives paſſage to the poſterior interoſſeous veſſels; ſtronger below, where we find another opening for the paſſage of the anterior interoſſeous veſſels. On the poſterior ſurface of this ligament, and more eſpecially at the upper end, we often find flat bands of fibres decuſſating it: they have been deſcribed under the name of the poſterior tranſverſal chord.

The inferior articulation between the radius and ulna, or that at the carpal ends of theſe bones, is provided with a ſynovial capſule, and a triangular fibro-cartilage interpoſed between the ulna and the bones of the carpus, and filling the vacancy obſerved between them in the ſkeleton.

This triangular cartilage is fixed by its baſe to the prominent edge which divides the articular cavity at the bottom of the radius, from that which receives the capitulum of the ulna. It is attached by its ſummit to the groove between the capitulum and the ſtyloid proceſs. Its edges are united to the ſynovial membranes of both articulations, the radio-carpal and the radio-cubital. Its upper and lower ſurfaces are concave and ſmooth, the ſuperior correſponding to the lower ſurface of the ulna. It is occaſionally incomplete at the baſe, allowing of the contact of the two capſular membranes juſt mentioned.

The capſular membrane is looſe, ſo as not to impede the extended rotation of the radius. It is continued from the upper ſurface of the inter-articular cartilage over the articular ſurfaces of the radius and ulna. It is ſometimes covered here and there by a few ſcattered ligamentous fibres, which are in many inſtances ſcarcely obſervable.

The motions of the bones of the fore-arm, between themſelves and their powers of reſiſtance.—We have hitherto conſidered the fore-arm only in its relation to the arm, in which the ulna was more eſſentially concerned; the movements in the preſent caſe depend chiefly, and almoſt excluſively, on the radius, and are neceſſarily communicated to the hand with which it is articulated below, the ulna concurring but little in the conſtruction of the joint of the wriſt. Theſe bones are thus diſpoſed inverſely as to importance in the joints of the elbow and wriſt: above, the ulna plays the principal part, the radius being acceſſary only; whereas below, the ulna is of comparatively little importance, the radius of the greateſt. Their form is accommodated to the different uſe of each: the ulna large above and ſmall below; the radius of little volume at its upper extremity, broad and ſolid at its lower, where it ſupports the hand. This double oppoſition in the form of the bones is not only accommodated to their functions, but renders the ſolidity of the fore-arm nearly equal throughout.

out. The radius, however, from its more direct connection with the hand, more immediately ſuſtains any effort impreſſed on the latter, as in puſhing violently, or falling, and is often fractured under ſuch circumſtances. Still the reſult of the general mechaniſm will be, that the ſame bone, not having to ſupport the motions of the two joints, the elbow and wriſt, motions which are often ſimultaneous, fractures and diſlocations are the leſs likely to occur.

The radius may be rolled on the ulna inwards and outwards. In the former caſe, ſuppoſing the radius to be horizontal, the palm of the hand is turned downwards, and the motion called on that account pronation; in the latter it is turned upwards, and the motion called ſupination. In pronation, which is the moſt common poſition, the humeral end of the radius turns on its axis in the hoop formed for it by the leſſer ſigmoid cavity dna the annular ligament, while the carpal extremity rolls over the lower end of the ulna, tracing an arc of a circle. In this ſtate the relative ſituations of the bones are changed, the radius croſſing the ulna, and diminiſhing the ſpace between them. If pronation be carried forcibly too far, a diſlocation may take place in either articulation; more readily in the lower, on account of the greater extent of motion, and leſs ſtrength of reſtraining ligaments; in the upper, the radius does not quit its ſituation, and is ſecured by a very ſtrong ligament, beſides the powerful ſupport of the muſcles attached round it. In ſupination the radius moves in the contrary direction, until it becomes parallel to the ulna, beyond which it cannot go. If it is forced beyond theſe limits a diſlocation of one of the articulations muſt enſue, moſt probably of the lower. A great obſtacle to luxations of this joint, either in pronation or ſupination, is found in the triangular fibro-cartilage at the lower end of the bones, which is very ſtrong, and which muſt neceſſarily be torn.

Although at firſt ſight one might be diſpoſed to imagine the ulna an immoveable fulcrum, round which the radius rolls, it is certain that in pronation the carpal end of the ulna paſſes outwards, in ſupination in the contrary direction, ſo that it traces arcs of a circle in a contrary way to the carpal end of the radius. Of this any one will be effectually convinced by obſervation or experiment. But as the ulna cannot roll on the lower end of the humerus, it neceſſarily involves the latter bone in the execution of theſe motions, which it thus aſſiſts by its powers of rotation. Pronation and ſupination then depend not only on the rotation of the radius, but on the oppoſite motion of the ulna, and the rotation of the arm. The latter of theſe is very much more ſenſible if the motions take place when the fore-arm is extended on the arm, than when it is bent: in the former caſe, from the diſpoſition of the bones and ligaments, any rotatory motion of the ulna is impoſſible, in the latter it may exiſt in a ſlight degree.

We have obſerved that the diſpoſition of the bones of the fore-arm is ſuch as to offer the beſt poſſible reſiſtance to external efforts: nor is their poſition as to theſe motions leſs favourable, the head of the radius lying a little before the ulna, and the breadth of its carpal extremity removing its axis from the lower end of the ulna, ſo as to increaſe and facilitate the pronation and ſupination of the hand, offering at the ſame time a broad baſis for its ſupport.

The hand—forms the fourth and laſt diviſion of the ſuperior extremity; it is articulated with the lower end of the fore-arm. It varies conſiderably in ſize and form in different individuals: moſt commonly is comparatively ſmaller in females. We diſtinguiſh in it two ſurfaces, a dorſal and a palmar; two edges, a radial and ulnar; and alſo an upper or anti-brachial, and a lower or digital end. It is compoſed of twenty-ſeven bones, which have been arranged under the different titles of carpus, metacarpus, and fingers.

The Carpus.—The carpus, or wriſt, is oval tranſverſely, convex on its dorſal, hollowed on its palmar ſurface, where it gives paſſage to the flexor tendons. This hollow is bounded laterally by four eminences reſulting from different bones of the carpus, which give attachment to a ſtrong ligament confining the tendons in their ſituation. It is convex at the edge next the fore-arm, offering a number of irregular articular ſurfaces at the border next the metacarpus. It is formed by two rows of ſmall irregularly ſhaped bones, the upper range called anti-brachial, the lower metacarpal. Each of theſe ranges is compoſed of four bones: thoſe in the anti-brachial row, commencing from the radial edge, are the ſcaphoides, lunare, cuneiforme and piſiforme; in the metacarpal row the trapezium, trapezoides, magnum and unciforme. Although varying much in figure, they have ſome characters in common, which allow of our deſcribing them with tolerable preciſion, without rendering confuſed or obſcure our ideas of their mutual relations. We diſtinguiſh in each bone ſix ſurfaces, or ſides; an upper or anti-brachial, a lower or metacarpal, an anterior or palmar, a poſterior or dorſal, an outer or radial, and an inner or ulnar.

The ſcaphoides, ſo called from a ſuppoſed reſemblance to a boat, is the largeſt bone of the firſt row. It is ſomewhat oval in figure, the long axis being directed obliquely from above outwards and downwards. The upper ſurface is convex, triangular, articulated with the radius; the lower is alſo convex, correſponding to the oppoſite ſurfaces of the trapezium and trapezoides. The poſterior narrow, and grooved by the inſertion of ligaments; the anterior long and contracted, concave towards the fore-arm, convex and projecting below, forming one of the eminences before mentioned. The outer, or radial ſide, is rough for the attachment of the external lateral ligament of the wriſt; the internal preſenting a double articular ſurface, the upper narrow and convex, connected with the os lunare; the lower broad and concave, forming part of the articular cavity for the reception of the os magnum of the ſecond row.

The lunare, or ſemi-lunare, has obtained its name from the figure of one of its articular ſurfaces, which reſembles a creſcent. It is not ſo elongated in form as the laſt bone; convex and triangular above when articulated with the radius; concave below, narroweſt in its tranſverſe diameter, articulated with the os magnum, and in a ſmall degree with the unciforme; rough and unequal on the anterior and poſterior ſurfaces for the attachment of ligaments, the anterior ſide the ſmalleſt; the outer face narrow, ſmooth, in the form of a creſcent, with the convexity upwards in contact with the ſcaphoides; the inner alſo ſmooth, plane, articulated with the cuneiforme.

The os cuneiforme (triquetrum of Albinus) leſs in volume than the preceding, oblong and ſomewhat pyramidal in ſhape, its baſe next the os lunare, its apex directed obliquely inwards and downwards. The upper ſurface is convex, articulated with the bottom of the ulna by the intervention of the triangular fibro-cartilage before mentioned; the lower oblique, concave, articulated with the unciforme; the anterior preſents on its inner ſide a flat circular articular facet articulated with the piſiforme, on its outer it is rough for the attachment of ligaments; the poſterior and internal are alſo unequal and rough for ſimilar purpoſes; the external or radial ſurface is plane and ſmooth, articulated with the lunare.

The os piſiforme (ſubrotundum of Albinus) has obtained its name from its rounded figure. It is the ſmalleſt of the bones of the carpus. On its poſterior ſurface we obſerve a ſlightly hollowed articular ſurface, where it reſts on the laſt deſcribed bone, "aſſidens patellæ in modum, aut ſeſamoidei," (Alb.) With this exception the bone is convex on all ſides, projecting beyond the plane of the other carpal bones, rough, and unequal, giving attachment above to the flexor carpi ulnaris, below to the abductor of the little finger, and before to the annular ligament of the wriſt. It conſtitutes one of the four prominent points of the palmar ſide of the carpus.

The trapezium (multangulum majus, Alb.) is the firſt bone on the radial ſide of the ſecond range of carpal bones, and lies ſomewhat anterior to them. Above it offers a concave articular ſurface, ſemi-circular, oppoſed to the ſcaphoides; below another, convex antero-poſteriorly, concave tranſverſely, articulated with the metacarpal bone of the thumb; on the front rough, with a deep groove at the upper end for the paſſage of the flexor carpi radialis; the outer edge of the groove giving attachment to the annular or tranſverſe ligament, and forming one of the eminences already mentioned; on the back and outer ſides rough and unequal for attachment of ligaments; on the inner ſide are two articular ſurfaces; the upper, large and concave, connected with the trapezoides; the lower, narrow and plane, for the metacarpal bone of the fore-finger.

The trapezoides (multangulum minus, Alb.) is very irregular in figure, placed like a wedge between the laſt and the following bones, the baſe of it being poſterior, the point towards the palm. The upper ſurface is concave, quadrilateral, and articulated with the ſcaphoides; the lower divided by a convex line croſſing from before backwards, adapted to the hollow of the metacarpal bone of the fore-finger; the dorſal or poſterior, convex, rough and broad; the anterior poſſeſſing the former characters, but much ſmaller; the external, convex articulated with the trapezium; the internal or ulnar, ſmaller and concave, ſmooth anteriorly where articulated with the following bone, rough behind for ligamentous attachments.

The os magnum (capitatum, Alb.) is the largeſt of the eight; longeſt in its vertical axis, rounded into an articular head above, (from whence it derives its name,) of a quadrilateral form below. The upper articular ſurface is convex, divided by a prominent line into two portions, one for the ſcaphoides, the other for the lunare; the lower is divided into three facets, the external articulated with the ſecond bone of the metacarpus, the middle the largeſt of the three, concave, ſupporting the third, the internal or poſterior very ſmall, plane, oppoſed to the inner edge of the fourth; the palmar and dorſal ſurfaces, rough and unequal for ligaments, the latter the largeſt of the two, the external narrow, articulated with the trapezoides; the internal of greater extent than any of the preceding, ſmooth above where contiguous to the unciforme, rough below, giving attachments to ligaments.

The unciforme (os hamatum; cuneiforme Alb.) completes the ſecond row of carpal bones, being the laſt on the ulnar ſide. Above is a rounded angle oppoſed to the lunare; below a ſmooth ſurface, convex tranſverſely, the outer ſurface ſupporting the fourth, the inner the fifth metacarpal bone; on the anterior ſide we obſerve, below, a curved proceſs projecting forward, to which the annular ligament is attached, as alſo ſome muſcles of the little finger; it forms the laſt of the four eminences referred to before; the ſuperior part of this ſurface is narrow, unequal, but ſmooth, giving attachment to ligaments; the poſterior ſurface is broad, triangular, and rough; the external offers an articular ſurface above, in contact with the os magnum, is rough below for ligamentary connections; the internal is directed obliquely, preſenting a curved, oblong, articular facet, and a rough line below it; the former oppoſed to the cuneiforme, the latter ſerving for attachments to ligaments.

The bones of the carpus reſemble each other in ſtructure; compoſed of a cellular or ſpongy ſubſtance, externally covered by a thin layer of compact bone. They are developed from ſingle points of oſſification, which do not commence till after birth. At that period they are entirely cartilaginous, diſtinct, well marked, and not at all proportionably larger than when fully oſſified, and on this account differing from the cartilaginous extremities of the long bones.

The articulation of the fore-arm with the carpus, or joint of the wriſt.—The ſuperior ſurfaces of the ſcaphoides, lunare, and cuneiforme, form by their union a common convex ſurface, oblong tranſverſely; each bone is covered by its proper cartilage, firmly united to the next by an intervening band of a fibro-cartilaginous ſtructure, which ſeparates this joint from the articulations of the carpal bones between themſelves. The lower extremity of the radius, and the triangular cartilage at the bottom of the ulna, form an elliptical concave ſurface, which receives the oppoſite convexity of the carpus, ſo that the ſcaphoides and lunare are oppoſed to the radius, and the cuneiforme to the inter-articular cartilage which ſeparates it from the ulna. The joint is ſtrengthened by ligaments on each ſide, and alſo before and behind, and lined by a ſynovial membrane.

The external lateral ligament is attached above to the ſtyloid proceſs of the radius; it advances forward a little as it deſcends, and is fixed on the outer ſide of the ſcaphoides. The fibres of which it is compoſed diverge below, and become continuous with the anterior ligament: we can often trace them on to the trapezium. Its form is irregular, and by no means defined, the edges being variouſly connected with the parts around it. The internal lateral ligament proceeds from the ſtyloid proceſs of the ulna, and is attached below to the inner ſide of the os cuneiforme. it is implanted alſo by ſome of its anterior fibres into the annular ligament, and piſiforme bone.

The anterior ligament is broad, and flat; fixed above to the anterior part of the ſtyloid proceſs of the radius, and the whole anterior edge of the articular cavity; from hence the fibres deſcend obliquely inwards, and are fixed below in an irregular line to the ſcaphoides, lunare, and cuneiforme; ſome fibres go to the piſiforme, the greateſt number are attached to the lunare. The flexor tendons lie in front, the ſynovial membrane immediately behind it. The poſterior ligament is not ſo broad as the preceding, and more evidently fibrous; its direction is nearly the ſame, being fixed above to the poſterior border of the articular hollow of the radius, below the lunare, and cuneiforme; it is covered by the extenſor tendons. Theſe ligaments are in nowiſe connected with the ulna, ſo that they cannot in any ſituation impede the rotation of the radius on that bone. The ſynovial membrane is ſpread over the articular ſurfaces of the radius, and triangular cartilage above, and the three bones of the carpus below; it is reflected between them under the ligaments, appearing in the intervals between their fibres in ſeveral ſpots. The joint of the wriſt is ſtrengthened on every ſide by ſtrong and numerous tendons, ſome of which are inſerted in its vicinity, others cloſely bound to its ſurface by ſtrong tranſverſe ligaments as they paſs from the fore-arm to the hand and fingers. The ſecurity derived from this conſtruction muſt be very great, without it the joint would preſently yield to the many violent impulſes it has to ſuſtain, to which the ligaments alone would offer a very inadequate reſiſtance.

The motions of the carpus on the fore-arm—are thoſe of flexion, extenſion, lateral inclinations or abduction, and adduction, and circumduction. From the cloſe connection of the carpal bones between themſelves, and with the reſt of the hand, theſe motions of the carpus may be conſidered at the ſame time as general motions of the hand. Thoſe of pronation and ſupination depend on the motions of the bones of the fore-arm, and are in nowiſe dependant on this joint.

In flexion the articular convexity of the carpus glides from before backwards in the correſponding cavity of the fore-arm, and the poſterior ligament and extenſor tendons are ſtretched; it may be carried to nearly a right angle without violence; an effort preſſing beyond this point would ſtrain, and might certainly diſlocate the bones.

In extenſion an oppoſite ſucceſſion of phenomena occurs, it is the anterior part of the joint which has the effort to ſuſtain. This motion is not confined to the bringing the carpus and hand into the ſame ſtraight line with the fore-arm, but may be continued in the oppoſite direction to ſome extent, ſo as to make them form a conſiderable angle with it on the dorſal aſpect. The freedom of motion enjoyed by the carpus in this ſenſe is ſubſervient to many of the important uſes of the hand, and is not to be found in other analogous joints, where the power of flexion is greater, and that of extenſion limited to bringing the oppoſite bones into the ſame axis, as in the elbow, knee, &c. The lateral motions, thoſe of abduction and adduction, are more confined, eſpecially the laſt. The lateral ligaments are alternately ſtretched and relaxed, preventing their too great extent. Circumduction is alſo confined to narrow bounds, more particularly ſo when pronation and ſupination are not concerned in producing it.

The articulations between the carpal bones—all communicate together, being lined by a continuous ſynovial membrane. The bones lie in cloſe appoſition, and are bound firmly by ligaments on the palmar and dorſal ſurfaces, ſome by ligaments paſſing deeply between them. The three firſt bones of the upper row are in contact by nearly plane ſurfaces covered by cartilage, the ſcaphoides connected with the lunare, the latter with the cuneiforme. The palmar ligaments uniting them lie deep under the anterior ligament of the wriſt, the fibres of each paſſing tranſverſely from bone to bone. The dorſal ligaments are more diſtinct, the fibres longer as they are more ſuperficial, they have the ſame direction as the former. The ſuperior, or interoſſeous ligaments, have been already mentioned in ſpeaking of the joint of the wriſt, as ſeparating it from the articulations of the carpus. They are of cloſe condenſed texture, paſſing between the bones from before backwards, one joining the ſcaphoides to the lunare, the other this laſt bone to the cuneiforme. They are very narrow, the upper ſide ſmooth, covered by ſynovial membrane forming a poliſhed ſurface with the convexity of theſe bones, with the edges of whoſe cartilages they are continuous. The os piſiforme is placed without the ranks of the carpal bones, and has no communication with the common joint between them. It reſts by a ſlightly concave articular ſurface on a correſponding convexity of the cuneiforme; the joint is lined by a ſynovial membrane reflected from one to the other, ſtrengthened by ſcattered ligamentous fibres. Two bands of theſe, of conſiderable ſize and ſtrength, paſs from the lower ſide of the bone, one to the root of the metacarpal bone of the little finger; the other to the os unciforme. The piſiform bone is retained in its ſituation by theſe, and, in ſome meaſure, alſo by the abductor muſcle of the little finger, to which it gives attachment. Above we obſerve ſome ligamentous fibres paſſing from it to the ulna, and the inſertion of the flexor carpi ulnaris. It performs the office of a patella, or ſeſamoid bone, for this latter muſcle "poſitum porrectumque inter ejus tendinem, ligamentumque ad os metacarpi digiti auricularis pertinens." Its motions are very limited; it forms, together with its connections above and below, a large portion of the channel through which the flexor tendons glide.

To form the articulation between the firſt and ſecond row we find the ſcaphoides touching the trapezium and trapezoides, forming, in conjunction with the lunare, a cavity for the reception of the head of the os magnum, and the cuneiform bone ſupporting the unciforme. The reſpective articular ſurfaces are covered by a thin cruſt of cartilage, and preſerved in their ſituations by palmar, dorſal, and lateral ligaments. The palmar ligaments are ſhort and ſtrong, formed by fibrous bands, paſſing from one row to the other in different directions; the moſt ſuperficial are confounded with the anterior ligament of the wriſt. The dorſal ligaments reſemble them in their paſſing from the upper row to the lower, but are too irregular in ſize and direction to allow of ſpecific deſcriptions. Indeed they are both ſo mixed with the ſurrounding ligamentous fibres as ſcarcely to admit of diſtinction. Of the lateral ligaments, the external is the ſhorteſt and ſtrongeſt, paſſing from the ſcaphoides to the trapezium; the internal ſtretched between the cuneiforme and unciforme.

The bones of the ſecond row are in contact by cartilaginous ſurfaces, and connected by ligaments, as thoſe of the firſt. The dorſal tranſverſe ligaments, are very diſtinct, one between every two correſponding bones; the palmar are not ſo well defined, the fibres of each being ſhorter and more numerous, as they are more deeply ſeated. We can obſerve one band, paſſing from the trapezium to the os magnum in front of the trapezoides, independent of thoſe between the contiguous bones. Between the unciforme and os magnum is a ſtrong collection of fibres paſſing from ſide to ſide through the depth of the carpus, adhering firmly to ſuch parts of the correſponding bones as are not covered by cartilage. A ſimilar connection exiſts alſo between the os magnum and unciforme.

The ſynovial membrane is continued from one articular facet to another, lining the ligaments we have deſcribed, appearing in many places between their fibres. Nor does it form a continued ſurface only between the carpal bones, it is extended below into the joints, between the carpus and metacarpus; not always, however, into thoſe formed above by the os magnum and unciforme. Owing to this general communication, diſeaſe of one articular ſurface is preſently propagated to the whole; in this reſpect it muſt be conſidered only as a ſingle joint.

The piſiform bone is in nowiſe concerned in the mechaniſm of the carpus; its uſes have been mentioned above. So cloſely are the bones of each row bound one to another, that they allow of ſcarcely any perceptible gliding motion. The articulations between the two rows allow of a more ſenſible movement; though this is confined to narrow limits. It reſembles ſomewhat that obſerved in the joint of the wriſt; they can be bent, and extended a little on each other, as well as inclined laterally; the firſt of theſe is the moſt evident. The little motion they poſſeſs is produced principally by the articulation of the head of the os magnum, which has the greateſt effort to ſuſtain, and has been ſometimes luxated backwards. Notwithſtanding the obſcurity of movement in the carpal bones, it co-operates in increaſing the mobility of the hand, whilſt at the ſame time, by the number of articulating ſurfaces, impulſes may be to a certain degree weakened.

Before we enter on the latter point, it will be proper to take ſome notice of another ligament, materially affecting the ſolidity of the carpus, though deſtined but in a ſecondary way for this purpoſe, its firſt office being to confine the flexor tendons in their paſſage to the fingers. The annular ligament in front of the wriſt, (ligamentum armillare, ligamentum carpi proprium,) paſſes from the eminences formed by the piſiform and unciform bones to the oppoſite ones of the ſcaphoides and trapezium, completing the canal for the flexor tendons. It is compoſed of very ſtrong and thick fibres, becoming gradually thinner above and below; rough ſuperficially, lined behind by a ſynovial burſa. It gives attachment to ſeveral muſcles of the thumb and little finger. The fibres are all tranſverſe, numerous and compact, ſecuring, in addition to its other uſes, the arch formed by the carpal bones. The carpus then derives its firmneſs from the large ſurface of the articulating facets in compariſon with the ſmallneſs of the bones, from their number, from the numerous ligaments, and from the arched form reſulting from the connection of the whole. It is further ſtrengthened by numerous tendons, the flexors in front, the extenſors on its dorſal ſurface. Another cauſe of the ſolidity of the carpus is, that the articulations between the two ranks are not in the ſame tranſverſe line, the unciforme, and more eſpecially the head of the os magnum, mounting far beyond the level of the trapezium and trapezoides, ſo that any impulſe would not act on all at once, and cauſe a general diſplacement, the effort and the injury muſt be partial, confined to the articulations between one or two of the bones.

The metacarpus (die mittelhand, Germ.) is compoſed of five bones, reſting on the carpus above, giving ſupport to the thumb and four fingers below. They are ſtrong, thoſe ſupporting the fingers parallel to each other, the other a little anterior, and capable of altering its poſition. The intervals between them are filled by muſcles ſo as to form a broad and ſolid body. The anterior face of the metacarpus is concave, conſtituting the palm of the hand, the poſterior convex, and forms the back. The bones are diſtinguiſhed, from the connections below, into the metacarpal bones of the thumb, the fore, the middle, the ring, and the little fingers, or we claſs them numerically, beginning on the radial ſide with the metacarpal bone ſupporting the thumb. Of theſe diviſions we ſhall adopt the latter. The firſt metacarpal is the largeſt, and ſhorteſt of the whole; the ſecond and third are nearly of the ſame length; the fourth and fifth are ſucceſſively ſhorter and ſmaller. They are all ſomewhat concave before, and flat behind, preſenting ſeveral more or leſs acute angles; larger at each extremity, the upper angular and unequal, the lower forming a convex head, compreſſed laterally, with an articular ſurface terminating on the palmar ſide in two prominent points; ſmalleſt in the middle of the body of the bone, increaſing gradually in ſize above and below. In conſidering the diſtinguiſhing characters of each metacarpal bone, we ſhall obſerve them as ſeen on the carpal extremities, the bodies, and the digital extremities of each ſucceſſively, and not tire the reader by a ſeparate deſcription of the ſeveral bones, in which it would be impoſſible to avoid repetition, and which muſt neceſſarily be of greater length.

At the upper or carpal end of the firſt metacarpal bone we obſerve an articular ſurface convex tranſverſely, ſlightly concave in the oppoſite direction, oppoſed to the trapezium. It is ſurrounded by ligaments, and gives attachment on the outer ſide to the extenſor oſſis metacarpi pollicis.

In the ſecond are three articular ſurfaces, the middle concave, correſponding to the prominence of the trapezoides; the external ſmall and flat, articulated with the trapezium; the internal divided into two portions, the upper articulated with the os magnum, the lower with the following bone. The circumference of this extremity is rough, and gives attachment to ligaments. On the palmar ſide is a rough ſpot, which gives attachment to the flexor carpi radialis; on the dorſal a tubercle, into which the extenſor carpi radialis longior is inſerted.

In the third a quadrilateral articular ſurface oppoſite to the os magnum, bounded before and behind by inequalities, giving attachments to ligaments; on the outſide by a ſmooth facet articulated with the preceding bone; on the inſide by two ſmall round articular ſurfaces, ſeparated by a hollow contiguous to the following bone. At the external dorſal angle is a pyramidal eminence (proceſſus ſtyliformis), and cloſe on the inner ſide the inſertion of the extenſor carpi radialis brevior.

In the fourth, at the top, a double articular ſurface, accommodated to thoſe of the os magnum and unciforme, ſurrounded before and behind by rough points for ligamentous attachments, on the outſide by two prominent articular facets, correſponding to thoſe of the laſt bone; on the inſide by a ſlightly concave ſurface articulated with the following.

In the fifth, a broad articular ſurface, convex from before backwards, concave tranverſely; ſlanting outwards and upwards, oppoſed to the unciforme, bounded before and behind by rough ſurfaces for ligaments, on the outſide by a ſmall articular facet connected with the laſt bone on the inſide by a tubercle which gives attachment to the tendon of the extenſor carpi ulnaris.

The bodies of the metacarpal bones are all concave anteriorly, and ſlightly convex on their dorſal ſurface. Although rather irregular in figure we can diſtinguiſh in them four ſides, an anterior, a poſterior, an internal, and external. In the firſt the poſterior ſurface is broad; in the three next we obſerve above a prominent line running lengthwiſe, which ſoon bifurcates, forming the lateral boundaries of a flat triangular ſurface, the breadth of which increaſes as it approaches the digital extremity; in the laſt an angular line, running diagonally from the inner ſide of its carpal end to the outſide of its lower extremity. In all of them the poſterior ſurface is covered by the extenſor tendons.

The anterior or palmar ſurface preſents alſo a longitudinal riſing line, generally more prominent towards the lower end. It ſeparates the attachments of the interoſſei muſcles, and has ſomewhat different directions in the ſeveral bones. In the firſt rounded, covered by the opponens, and flexor brevis pollicis; in the third giving attachment above to the latter muſcle, below to the adductor pollicis. The lateral ſurfaces of theſe bones are broad, inclined obliquely in various directions, giving attachment to muſcles. In the firſt they are compreſſed and rounded, the outer ſide giving attachment to the opponens, the inner to the firſt external interoſſeus (the abductor indicis of Albinus). In the laſt the inner or ulnar ſide gives attachment to the adductor oſſis metacarpi minimi digiti; the outer ſide, as well both ſides of the other metacarpal bones, give attachment to and are covered by the external and internal interoſſeous muſcles.

The digital extremities are in all convex, and nearly alike in figure. On the palmar ſide of the firſt we obſerve two ſlight depreſſions correſponding to the ſeſamoid bones in front of the joint; on the ſides of the articular ſurfaces of each deep hollows for ligaments, which ſecure the articulations between theſe bones and the fingers.

The metacarpal bones reſemble in ſtructure and formation the other long bones. At the period of birth the extremities are cartilaginous, oſſification commencing in the body of the bone in the embryo of three months.

In the preceding deſcription we have reckoned five metacarpal bones, according to the plan followed by the moſt eminent anatomiſts. By many the firſt metacarpal bone has been omitted, and deſcribed as the firſt bone of the thumb, which they conſider as compoſed of three bones, like the fingers. By Albinus the metacarpus is divided into two portions, one, compriſing the four laſt bones, he calls the metacarpus manus; the other, the metacarpus pollicis.

The articulations between the bones of the carpus and metacarpus are nearly ſimilar in all but the firſt. The articular ſurface at the upper end of the metacarpal bone of the thumb is convex and concave in oppoſite directions, adapted to the correſponding ſurface of the trapezium. The joint is ſurrounded by ligamentous fibres paſſing from one bone to another, amongſt which the external and dorſal are the moſt ſtrongly marked, and the moſt in number, the internal and anterior are continued on to the annular ligament. It is lined by a diſtinct ſynovial membrane. The diſpoſition of the ligamentous fibres is ſuch as to form a capſule round the articulation, like that obſerved in the ſhoulder joint, but not ſo looſe. The whole is ſupported by the muſcles and tendons of the thumb. The ſecond metacarpal bone is articulated with the trapezium, the trapezoides, and the os magnum; the third with the latter only; the fourth with it and the unciforme; the fifth with the laſt alone. The ſurfaces are covered by cartilages continuous with thoſe forming the joints between the metacarpal bones themſelves, and lined by a common ſynovial membrane with occaſional exceptions, as mentioned when ſpeaking of the carpus. The ligaments on the dorſal ſurface paſs in different directions from the lower row of carpal bones, to the upper end of thoſe of the metacarpus. There are two for the ſecond of theſe, one from the trapezium, the other from the trapezoides; the third has but one from the os magnum; the fourth two, paſſing from this bone and the unciforme; the fifth a ſingle band from the latter. They are all ſhort, flat, and compact. The palmar ligaments are leſs diſtinct, being confounded with thoſe around them. The moſt evident are, a band paſſing from the trapezium to the third and fourth metacarpals, confining in its paſſage the tendon of the flexor carpi radialis; and a band between the trapezium and firſt metacarpal.

The articulations of the metacarpal bones between themſelves.—The metacarpal bones, with the exception of the firſt, touch at both ends by lateral articular facets, which have been already deſcribed. The ſynovial membrane lining thoſe at the carpal extremity is open above, forming a free communication with the carpus. They are ſecured in their relations by tranſverſe ligaments at both ends. At the carpal end theſe are found on the palmar and dorſal ſurfaces; on the firſt of theſe the ſuperficial ligaments form a continued layer, paſſing from the ſecond to the laſt, the more deeply ſeated paſſing from bone to bone. The dorſal ligaments paſs acroſs between each bone. Beſides theſe, we find immediately below the articulations ſtrong ligaments paſſing deeply between the bones, uniting them moſt firmly together. At the digital end is a ſtrong tranſverſe ligament on the palmar ſide, the ſuperficial fibres paſſing from the firſt bone to the laſt, thoſe more deeply ſeated between each individual bone. It is covered in front by tendons and veſſels, behind it ſupports the interoſſei muſcles, and is united to the ligaments connecting the metacarpus with the fingers.

Among the bones of the metacarpus, the firſt enjoys very extenſive motions in every direction. The moſt important motion is that which brings the thumb in oppoſition to the fingers, and enables us to graſp the object before us; an office which made Albinus beſtow on it the emphatic name of "manus parva majori adjutrix." The freedom of this motion depends on the extent and obliquity of the articular ſurfaces, between it and the trapezium, and is favoured alſo by their being on a plane anterior to the reſt of the hand.

Circumduction of the thumb is very free towards the palm, very much leſs ſo in the oppoſite direction. The interval between this and the other metacarpal bones is highly advantageous in allowing of all its motions. The four laſt bones of the metacarpus are bound ſo cloſely together, as to allow of much individual motion. They can be brought cloſer together below, and bent a little forwards, ſo as to increaſe the hollow of the hand; this motion is moſt evident in the two laſt, thoſe of the ring, and little fingers. The four laſt bones of the metacarpus hold a middle rank, as to motion and ſolidity, between the carpus and fingers; above they partake of the firmneſs of the carpus, below approach nearer the mobility of the fingers.

The fingers, including the thumb,—are five in number. They are either reckoned numerically from the radial to the ulnar ſide, or diſtinguiſhed by proper names. The latter are in common acceptation. We count, therefore, the thumb as the firſt; the fore-finger or index as the ſecond; the middle finger as the third; the ring finger as the fourth; and the little finger as the fifth. By this arrangement we can immediately compare their relations to the metacarpal bones, which have been deſcribed alſo in a ſimilar numerical order. The fingers are compoſed of rows of long bones, placed vertically one beyond another, called *phalanges;* of theſe we find three in the fingers, properly ſo called, and two only in the thumb, the middle phalanx being wanting. They are diſtinguiſhed by the names of the firſt or metacarpal phalanx, the ſecond or middle, and the third or unguinal. As the correſponding bones of the ſeveral rows are eſſentially alike in all, we ſhall include them in one deſcription, noticing the peculiarities of each. We divide them into two extremities, and a body.

The firſt, or metacarpal phalanges,—are the largeſt, and longeſt of the three; of different lengths and ſize, the third being the longeſt, and all diminiſhing ſucceſſively in volume from the firſt to the laſt. They are convex on the dorſal ſurface, the tranſverſe convexity forming nearly half a circle; concave anteriorly, with ſharp angular edges laterally. At the ſuperior extremity we obſerve an articular ſurface, oblong tranſverſely, ſlightly hollowed, articulated with the correſponding bone of the metacarpus; a broad tubercle on each ſide giving attachment to lateral ligaments, divided anteriorly by a depreſſion, in which the flexor tendons paſs. In the thumb this extremity gives attachment to the abductor, the flexor brevis, and the adductor. The bodies of the phalanges are convex poſteriorly, covered by the extenſor tendons; concave on the palmar ſide with projecting edges, ſo as to form a kind of gutter, in which the flexor tendons are partly lodged; the edges give attachment to ligamentous ſheaths confining the tendons in their ſituation. The lower extremity offers an articular pulley, extended further and much broader on the palmar ſide than on the oppoſite, and the edges diverging conſiderably from behind forwards. On each ſide are depreſſions, which give attachment to lateral ligaments.

The ſecond, or middle phalanges,—are ſmaller and ſhorter than the firſt, which they reſemble much in general figure. The thumb poſſeſſes none. As to individual compariſon, they differ but little, that of the middle finger is the longeſt, the laſt belonging to the little finger the ſhorteſt and ſmalleſt. The upper extremity offers an articular ſurface croſſed antero-poſteriorly by a riſing line, correſponding to the oppoſite pulley of the firſt phalanx; on each ſide are tubercles giving attachment to ligaments. The body reſembles that of the metacarpal phalanx. About the middle of the anterior ſurface are two rough prominences, giving attachment to the divided tendon of the flexor ſublimis, and to a fibrous ſheath, which croſſes over it from ſide to ſide, confining alſo the tendon of the flexor profundus. Its poſterior ſurface gives attachment to a portion of the tendon of the extenſor communis. The lower extremity reſembles that of the firſt.

The third, or unguinal phalanges—are found, in all, five, diminiſhing in ſize from the thumb to the little finger, that of the former being by far the largeſt of the whole. The upper extremity or baſe (from a compariſon of the bone to a pyramid with its apex downwards), forms an articular ſurface, oval tranſverſely, with a convex line croſſing from before backwards, accommodated to the pulley of the middle phalanx; is tuberculated for ligaments on each ſide, giving attachment behind to extenſor tendons. The body is contracted; on its anterior ſurface the flexor profundus is fixed in the fingers, and flexor longus in the thumb. The lower extremity, or point, is flat, rounded, broader than the body, ſcabrous at the edges and on the anterior ſide, ſmoother behind, where it ſupports the nail.

The bones of the fingers have nothing peculiar in ſtructure or formation: the firſt and ſecond phalanges are formed from three oſſifying points, the third from only two. At the time of birth, their figure is well marked, and their formation very conſiderably advanced.

The articulations of the thumb and fingers with the metacarpus.—The convex heads of the metacarpal bones are covered by articular cartilages, in contact with thoſe lining the concave ſurfaces of the firſt digital phalanx. They are bound together by lateral ligaments, and ſtrengthened in front by the ſheaths of the flexor tendons, behind by the expanſion of the extenſors, on each ſide by the interoſſei muſcles. The lateral ligaments are attached above to the ſides of the lower end of the metacarpal bones, and divide as they deſcend into two diſtinct bands, which are fixed to the ſides of the correſponding bones of the firſt phalanx. They are ſtrong, formed of parallel fibres, lined on the inner ſurface by the ſynovial membrane. In front of the joint we find the tranſverſe ligament of the lower end of the metacarpus, which has been already deſcribed. The ſynovial membrane is looſe, particularly before lining the extenſor tendon in its paſſage behind over the joint, and appearing between the ligaments, which it alſo covers in front and on the ſides. In front of the joint of the thumb we find two ſeſamoid bones developed in the tendons of the flexor brevis, leaving a furrow between them, in which the tendon of the flexor longus paſſes. They reſt on the head of the metacarpal bone, gliding up or down, as the joint is bent or extended. They are ſometimes found in the articulations between the metacarpus and fingers. The motions enjoyed by this joint are thoſe of flexion, extenſion, abduction, and adduction; of theſe the firſt is by far the moſt conſiderable, the thumb poſſeſſing it in the leaſt, the little finger in the moſt extenſive degree.

The articulations between the phalanges are alike in all; the condyles, at the lower extremities of the firſt and ſecond phalanx, are covered by cartilage, and correſpond to the little hollows at the upper ends of the ſecond and third. They are covered by a ſynovial membrane, and connected by lateral ligaments, which paſs from bone to bone, reſembling thoſe of the preceding articulation. The ſynovial membrane is ſupported by theſe, as alſo by the extenſor and flexor tendons. It is ſo cloſely united to the extenſor tendon, at the upper end of the ſecond and third phalanx, that it is almoſt impoſſible to ſeparate them. It is continued much further down on the bone on the palmar, than on the dorſal ſurface, forming a little bag in front of the joint. The thumb has but one of theſe articulations, which is in every reſpect ſimilar to the joints between the phalanges of the fingers.

In this laſt part of the hand we obſerve an evident decreaſe of firmneſs, when compared with the metacarpus and carpus, and a proportionate increaſe of facility and extent of motion. The ſhortneſs of the bones, however, ſcarcely offering a reſiſting point to external impulſes, ſecures their relations, and leſſens the chance of fracture, though the fingers are more immediately within the action of ſurrounding bodies, and more expoſed to injuries than any other part of the limb. The joints of the phalanxes of the thumb and fingers allow only of flexion and extenſion; the latter cannot be carried beyond the ſtraight line, the former is very free; an effect which depends on the continuation of the articular ſurfaces in front, far beyond their extent on the dorſal ſurface, and which is provided for by a correſponding laxity of the ſynovial membrane. The advantages of this diſpoſition, for the important functions of the fingers, is ſo conſpicuous as to require no comment. In opening the hand, the fingers cannot be extended beyond the plane of the hand; from this ſituation they may be bent in various degrees, until their points touch the lower end of the metacarpus. This general flexibility, derived from the ſucceſſive rows of firm bones, and their peculiar modes of articulation, allows of the fingers being applied accurately to any body whoſe qualities we wiſh to examine, whatever be its figure. The decreaſing length and ſize of the ſeveral phalanxes permit us to ſeize objects conveniently and firmly, to retain them, however ſmall. The power we poſſeſs of moving them ſingly, or in different degrees, of touching the palm of the hand at any point of its ſurface, of ſpreading them laterally, of ſeparating one from another, &c. enables us to adapt their poſition to every poſſible uſe. In all the actions of the hand, the thumb holds a conſpicuous rank. Alone, it oppoſes the efforts of the other fingers, which are much longer, and bend, as it were, to meet the thumb, whenever we cloſe them on the object. With regard to the different lengths of the thumb, and ſeveral fingers, we may obſerve, that when ſeparated moſt widely from each other, by gently bending the points they may be brought to deſcribe nearly a circle on a plane ſurface, forming with the hollow of the palm a concave hemiſphere; from which ſituation they may be further contracted, till the ſeveral points meet: from this conſtruction they are ſuited to graſp equably and firmly bodies of a rounded form. The ſenſe of touch owes, in a great meaſure, its delicacy and perfection to the readineſs and preciſion with which the fingers can be applied to the object whoſe qualities we wiſh to examine. It would be almoſt endleſs to deſcribe the different motions of which they are ſuſceptible; they are ſo rapid in ſucceſſion, ſo varied in direction, extent, and power, ſo exquiſitely adapted to the innumerable offices they have to perform, as to conſtitute an inexhauſtible, not to ſay an inexplicable ſubject for diſcuſſion.

We conclude our hiſtory of the upper extremity, by ſome remarks on its powers of reſiſtance and ſuſceptibility of motion, as a complete member, enjoying the aſſemblage of all the properties we have deſcribed as reſulting from the mechaniſm of each diviſion.

The caſes in which the upper extremities are required to ſupport great efforts, or to oppoſe a powerful impulſe, are by no means ſo numerous or ſo frequent as in the lower limbs, where conſiderable exertion and reſiſtance are neceſſary, to ſupport the body in the ordinary attitudes. In the action of puſhing, the hand is applied to an object, the fore-arm and arm extended between it and the trunk forming a ſtraight lever, which conveys the weight of the latter on the body to be puſhed. In this motion the hand being inflected backwards on the fore-arm, the joint of the wriſt is ſoon fatigued by the diſtenſion and preſſure in front; the ſigmoid cavity of the ulna bears directly againſt the lower end of the humerus, the latter reſts on the glenoid cavity of the ſcapula, which is fixed firmly by its muſcles and the clavicle.

It is only, however, when the arm is directed outwards, that it bears directly on the glenoid cavity; if it be turned forwards or backwards, the capſular ligament and the ſurrounding muſcles ſuſtain the effort. The firſt circumſtance is moſt favourable to firmneſs and continued reſiſtance; and we may obſerve, that when at liberty to chooſe our attitude in puſhing with one arm, we always place it in ſuch a direction as to bring it to bear directly on that cavity. For inſtance, if the object be in front, we turn ourſelves ſo as to bring the ſide of the body correſponding to the limb we are about to exert oppoſite to the object. In preſſing downwards, in reſting on the arm, &c. the mechaniſm is nearly the ſame, as far as regards the hand, which is ſo much extended on the fore-arm as to form an angle with it behind, while the fore-arm is placed in the ſame line with the arm, the joint of the elbow being fixed and immoveable. The difference depends only on the change of ſituation which takes place in the joint of the ſhoulder, the head of the humerus preſſing more or leſs advantageouſly, as the direction of the preſſure varies from the relative poſition of the object on which the limb reſts.

The beſt poſſible direction is where the arm is extended laterally, ſo as to bear on the glenoid cavity, the ſcapula being at the ſame time ſupported directly by the clavicle. It is underſtood that in every caſe the poſition of the limb is preſerved by muſcles, which are called on to act more or leſs, as that poſition is more or leſs favourable for ſuſtaining the effort, and become tired in the ſame proportion. This obſervation is more particularly applicable to the caſe in which the upper extremities have to ſuſtain the whole weight of the body, as in the inſtance of tumblers, when the hands are placed on the ground, and the body raiſed into the air, the upper exerting for a time the functions of the lower extremities. This attitude is both difficult and painful, from the want of ſufficient muſcles to maintain it, and from the ſmall extent of the articular ſurfaces. The wriſt ſuffers more particularly, as in marching on all-fours, becauſe theſe ſurfaces do not bear on each other, but on the front of the joint; the elbow is not ſo much diſtended from the conſtruction of the articulation; the ſhoulder-joint ſuffers almoſt equally with the wriſt, from the preſſure on its capſule. The upper extremities are articulated with the trunk in a plane poſterior to the lower; the line of gravity in the attitude above-deſcribed is anterior to the ſupport, and we find, conſequently, that to preſerve the balance, to counteract the tendency to fall forwards, the lower extremities are thrown conſiderably backwards.

The motions of the upper extremity are ſo numerous and varied, as ſcarcely to admit of claſſification; they are ſo familiar as not to require deſcription. The mechaniſm by which they are performed has been conſidered in treating of the ſeveral articulations, and may readily be applied to any caſe; we ſhall now only briefly recapitulate the more material points. The ſhoulder is the centre of motion of the whole limb; the arm gives the general movement, the parts below thoſe which are more partial. The motions of the ſhoulder affect the whole limb; as we deſcend, the actions are more and more confined. A finger may be employed while the arm is motionleſs; if the latter is moved, all below muſt partake of the motion. It is from the combination of the ſeveral partial motions that the increaſe and variety of the whole are derived, and theſe are multiplied the lower we go. The hand enjoys the individual motions of its component parts; a general motion from the joint of the wriſt; a more general ſtill from the connection of the bones of the fore-arm and the elbow, which is increaſed to a ſtill greater extent by the ſhoulder joint and ſhoulder. The motions then may be more compound as we deſcend, as well as more partial, becauſe each part enjoys the motion reſulting from its proper articulation, in conjunction with all thoſe above it. This general action of the parts of the upper extremity is obſervable in ſeizing or graſping any body, or in embracing, where all the articulations are *bent*, or in the oppoſite actions of ſpreading the arms, or *extending* the whole limb in different directions, &c. It is more commonly ſeen under caſes where the different joints are inflected variouſly at the ſame time, ſome extended, and others bent, theſe motions being often alternate. All theſe modifications of action may be obſerved in puſhing, pulling, climbing, graſping a diſtant object, ſwimming, ſtriking, &c. &c. In ſhort, in all the familiar exerciſes of the upper extremity we are conſtantly in the habit of performing. We cannot conclude without hinting at thoſe impreſſive actions of the upper extremity, which form a mute language employed moſt emphatically in aiding the expreſſions of our paſſions, or our will; it is enough to ſay, they are as numerous and varied as the feelings which bring them into play.

The lower extremity—is divided, as the upper, into four parts, *viz.* the hip, the thigh, the leg, and the foot, each of which has a more or leſs ſtriking analogy with the correſponding diviſions of the upper extremity. We ſhall examine their points of reſemblance and difference more minutely hereafter; at preſent, we would obſerve only, that the bones, which form the baſis of the lower extremity, are more maſſy and ſolid in their forms, and are hence adapted to their functions, as organs by which the reſt of the body is ſupported and moved. Their prominent character is ſolidity and firmneſs; in the upper extremity every thing is conſtructed for variety and quickneſs of motion.

The lower extremity is connected with the trunk by the articulation of the hip bone with the baſis of the vertebral column, the ſacrum; through which the whole weight of the body is tranſmitted to the bones of the hip. The connections of the two hip bones with the ſacrum behind, and with each other in front, form a bony cavity called the *pelvis*, the principal uſes of which are, to contain ſome important viſcera, to offer a baſis of ſupport to the trunk above, and two fixed points for the motions of the limbs below. It is in the laſt functions only that we ſhall have occaſion to notice the pelvis here; we ſhall not, therefore, enter into a deſcription of it as a whole, but attend to thoſe of its parts which bear on the preſent ſubject, and correſpond to analogous portions of the upper extremity.

The os coxæ, os innominatum, hip, or haunch bone, is the largeſt of the broad bones, placed laterally at the lower end of the trunk, connected with its fellow in front, by means of cartilage, and ſeparated from the oppoſite bone behind by the intervention of the ſacrum. The hip-bone is very irregular in figure, broad and flattened above, contracted and maſſy in the middle, and apparently more ſlender in the anterior and lower portions: it is curved ſo as to have its flat ſurfaces in almoſt oppoſite directions; the upper diviſion is flattened from ſide to ſide, the lower from back to front, the change of direction taking place in the middle portion. In young ſubjects this bone is formed of three ſeparate pieces; a ſuperior, called the *ilium*, an anterior, the *pubes*, and an inferior, the *iſchium*. In the adult they are ſo intimately united, that we can with difficulty trace their former line of ſeparation. We can ſee therefore no reaſon for deſcribing as diſtinct, what in its perfect ſtate forms but one ſolid bone. We ſhall conſider it as ſuch; but, not to deviate too much from common uſage, ſhall notice the different diviſions as we proceed, and afterwards particularly deſcribe their lines of union. We diſtinguiſh in the os innominatum two ſurfaces; an internal or pelvic, an external or femoral, and a circumference or border, which is again ſubdivided into ſeveral parts.

The external ſurface looks outward above, and forwards below; it is covered by ſtrong and numerous muſcles. The outſide of the broad upper diviſion, the dorſum of the ilium, is convex and concave in different parts; at the poſterior and ſuperior part is a rough eminence, which gives attachment to the gluteus maximus; below this a ſurface, concave and broad behind, convex and gradually narrowing in front, gives attachment to the fibres of the gluteus medius; it is bounded by the eminence juſt mentioned, by the upper edge or criſta of the ilium, and below by a ſemi-circular line, with the convexity upwards, paſſing forwards from a deep notch behind, (the great ſacroſciatic,) and terminating in the criſta of the ilium in front. The ſpace compriſed between this curved line and the deep articular cavity below, gives origin to the gluteus minimus; it is concave behind, and gibbous in front. At the anterior part, immediately above this cavity, is a rough impreſſion, where the curved tendon of the rectus cruris is fixed. The portion of the external ſurface, which is directed downwards and forwards, is very irregular in figure. Above is a deep and large cavity, called the acetabulum or cotyloid cavity; it forms nearly the half of a ſphere, lined by cartilage in its upper two thirds, the lower part a little deeper, lodging ſome cellular tiſſue, and the ſtrong ligament paſſing to the head of the thigh-bone. The margin of the cavity is irregular and waving, more prominent above than below, ſurmounted by a ligamentous ring, which makes the acetabulum ſtill deeper, interrupted towards the inner ſide by a notch, completed by a ligament which leaves only a ſmall opening for the paſſage of the articular veſſels; it gives attachment to the capſular ligament of the hip joint. The bone ſurrounding the cotyloid cavity is thick and maſſy, eſpecially at the upper and outer ſides; the cavity itſelf is directed obliquely outwards, downwards, and forwards. Below, and on the inner ſide of this cavity, is a large hole, of an oval ſhape, the foramen ovale, obturatorium, or thyroideum. Its long diameter is from above downwards, its edges are acute and rough, except at the upper part, where there is a ſmooth gutter directed obliquely from above inwards and downwards, in which the obturator nerve and veſſels are lodged. The groove is formed by the internal and external edges of the circumference croſſing each other at the top of the oval, the latter paſſing in front to a point called the ſpine of the pubes, leaving the oblique hollow between itſelf and the internal margin which paſſes up in the oppoſite direction. The foramen ovale is cloſed by a ligament attached to its edges every where but at the groove juſt mentioned, where it leaves a vacancy for the paſſage of the obturator veſſels, &c. In the female this foramen is ſmaller than in the male, and of a triangular figure. On the inner ſide of the foramen is a rough and unequal ſurface, broader above and below than in the middle, giving attachment to portions of the triceps, and the external obturator muſcle.

The internal or pelvic ſurface is concave, correſponding in its direction to the external or femoral, covered by muſcles which ariſe from it. The anterior part of the upper diviſion, the foſſa iliaca, is occupied by the iliacus internus muſcle; the poſterior is very ſcabrous and unequal, divided into two portions, of which the anterior is covered by cartilage, and articulated with the ſacrum, forming the ſacro-iliac ſymphiſis, reſembling ſomewhat in outline the human ear, the poſterior is convex and very rough, giving attachment to the ſtrong and numerous ligamentous fibres which connect this bone with the ſacrum above. Below the iliac foſſa, croſſing from the articular ſurface to the anterior angle of the bone, is a prominent angular line, forming a part of the ſuperior aperture of the pelvis, ſeparating the upper diviſion from the lower. The latter preſents a plane ſurface behind, broader above than below, giving attachment to the obturator internus and levator ani; in front of this is the obturator foramen, and in the inſide of the latter a narrower ſurface correſponding to the bladder above, giving origin to a part of the obturator internus below.

The circumference of the os innominatum is exceedingly irregular, with alternate prominences and hollows, and is divided into four portions, *viz.* a ſuperior, an inferior, a poſterior, and an anterior. The ſuperior margin bears the name of the criſta of the ilium; is convex, narrower in the middle than at the ends, and inclined outwards. The inner edge, or labium, gives attachment to the tranſverſalis abdominis, and quadratus lumborum; the external to the obliquus externus, the latiſſimus dorſi, and the faſcia of the thigh; the middle convex portion to the obliquus internus. The anterior margin is concave, and its lower half nearly horizontal. Its union with the criſta forms the anterior ſuperior ſpine of the ilium, which gives attachment to the tenſor vaginæ femoris, the ſartorius, and the upper end of that part of the tendon of the external oblique, called Poupart's ligament. Below this point is a ſlight notch, riſing again into another eminence, the anterior inferior ſpine of the ilium, from which the rectus crucis ariſes. This is ſucceeded by a ſmooth hollow, over which paſs the pſoas magnus, and iliacus, bounded by a protuberance called eminentia ileo-pectinea, into which the tendon of the pſoas parvus is implanted, when it exiſts. On the inſide of this there is an oblique ſurface, concave, triangular, with the baſe outwards, and the point inwards, bounded in front by a line which is continued from the external margin of the obturator foramen, behind by a ſharp ridge, the criſta of the pubes, which is continued from the tranſverſe line deſcribed as croſſing the pelvic ſurface. Over this concave ſpace paſs the crural veſſels. The anterior margin terminates by uniting with the inferior, at a right angle, called the angle of the pubes. A little before its end we obſerve on it a projecting point, the ſpine of the pubes, giving attachment to the pyramidalis, and the external pillar of the abdominal ring, formed by the tendon of the external oblique. The inferior margin is the ſhorteſt, preſenting above a perpendicular oblong ſurface, forming with the oppoſite bone, by the intervention of cartilage, the ſymphyſis pubis; below this the edge is thinner, forming with the oppoſite one the arch of the pubis, affording attachment to the gracilis, to portions of the triceps, to the corpus cavernoſum, the tranſverſalis perinei, and the erector penis, or clitoridis. The upper half of this bony plate is called the deſcending ramus of the pubis, the lower the aſcending ramus of the iſchium. The poſterior margin is the moſt irregular in its outline. Beginning from above we obſerve the angle formed by its junction with the ſuperior margin, the ſuperior poſterior ſpine of the ilium, an hollow ſeparating it from the eminence below, the inferior poſterior ſpine; a very deep notch forming part of the ſacro-ſciatic notch; a ſharp prominence, the ſpine of the iſchium, giving attachment to the ſuperior gemellus, the coccygeus, and the leſſer ſacro-ſciatic ligament; a ſmooth concave ſurface, over which the tendon of the obturator internus plays; and a broad eminence where it joins the inferior margin, the tuberoſity of the iſchium giving attachment, externally, to the quadratus femoris, and the great head of the triceps; within to the great ſacro-ſciatic ligament, and the inferior gemellus, in the interſpace to the biceps, the ſemi-tendinoſus, and ſemi-membranoſus.

The os innominatum is in ſtructure like the other flat bones; the two compact tables, encloſing the more cellular parts, touch each other in the middle of the iliac foſſa, and again at the depreſſion in the acetabulum. It is developed from three points of oſſification, at the angle of the pubis, the tuberoſity of the iſchium, and the middle of the upper diviſion, or ilium. The union of the bony plates proceeding from theſe points takes place between the ilium and pubes at the eminentia ileo-pectinea; between the latter and the iſchium, in the middle of the branch which forms the inner ſide of the foramen ovale, and the half of the arch of the pubes; between the iſchium and the ilium at the great ſacro-ſciatic notch. The junction of the three takes place in the acetabulum, which forms the principal point of union; the ilium makes the upper part of the cavity, the pubes the anterior, the iſchium contributing the principal ſhare, and completing it at the inferior and poſterior portions. The part which either bone takes in forming any of the principal features of the os innominatum will be immediately ſeen, by obſerving their lines of union with each other. At the time of birth the acetabulum, being far removed from the centres of oſſification, is wholly cartilaginous, as are alſo the different eminences, the ſpines, and the criſtæ. It is not till the time of puberty that all traces of cartilage are obliterated. The os innominatum is articulated with the ſacrum, by the ſacro-iliac ſymphyſis; with its fellow, by the ſymphyſis pubis; and with the thigh-bone by means of the cotyloid cavity. We ſhall ſay nothing of the two former of theſe connections, but that they are exceedingly ſtrong, and the bones bound ſo cloſely together, as not to allow of any perceptible motion; we ſhall deſcribe the laſt after having gone through the hiſtory of the thigh bone.

In commenting on the mechaniſm of the ſhoulder, we had to notice its articulation with the trunk, and the motions reſulting from its peculiar mode of connection; in the preſent inſtance we find an immoveable adherence of ſurfaces, which allows of no deviation from one determined poſition. In conſequence of this total want of motion, we ſhall not enter on the detail of the connections of the hip bone with the trunk, or with its fellow; they can influence the functions of the lower extremity no farther than by tranſmitting to it the weight of the body.

The oblique direction of the articular ſurfaces of the ſacrum, which gives it the form of a wedge driven between the two oſſa innominata, is well adapted to the purpoſe of tranſmitting ſecurely the weight of the trunk to the latter bones: the ſtronger the depreſſing impulſe, the more cloſely the ſurfaces are brought together; the ſhock muſt be violent indeed, which can in anywiſe looſen their connection. It is then through the medium of the ſacrum that every effort is propagated to the two hip bones, which in ſome poſitions are the immediate baſe o ſupport, while in others they continue the impulſe to the limb below. In the common attitude of ſitting, the trunk is ſupported on the tuberoſities of the iſchia; in progreſſion, or in ſtanding, on the cotyloid cavities. Theſe being at a diſtance from each other, facilitate the motions of the thighs, and increaſe their extent, the pubes executing one of the offices of the clavicle, in keeping the hip joints far aſunder, as the clavicle does thoſe of the ſhoulder. It will be ſeen, from the deſcription of the hip bone, that its ſurfaces and circumference give attachment to numerous and powerful muſcles, by far the greater number of which are deſtined to regulate, or to give vigour and effect to the motions of the thigh and leg, and to balance the varying weight above them.

The thigh—is the diviſion of the lower extremity between the hip and the leg. It is formed by a ſingle bone, called the *femur*, or *thigh bone.*

The femur is the longeſt bone of the body, the largeſt in volume, and the ſtrongeſt. It has a conſiderable curve forwards, is contracted in the middle, wider and more bulky at each extremity, one of which is called the upper, or *iliac*, the other the lower, or *tibial*.

The upper extremity includes three remarkable eminences; the head, ſupported by a long neck, and the great and little trochanters. The rounded head of the femur is received into the cotyloid cavity of the os innominatum; it forms more than half of a ſphere, directed upwards, inwards, and a little forwards; ſo that the greateſt part of its convexity is above, and its axis the ſame as that of the neck, which ſuſtains it. The convex ſurface is ſmooth, except juſt below the centre, where we find an hollow, which gives attachment to an inter-articular ligament; it extends further in front than behind, above than below, and terminates in a waving line at the neck. The latter contracts immediately below the head, and becomes a little flattened vertically, the upper edge remaining the wideſt; it is longer below and behind, on which aſpects it is alſo hollowed, than above and in front; joined by a broad baſis to the body of the bone, from which it ſtands off in a direction ſlanting upwards and inwards, advancing at the ſame time a little forwards, forming with it an angle more or leſs obtuſe. The length and obliquity of the neck vary conſiderably in different ſubjects, being in ſome nearly horizontal. The great trochanter is on the outer ſide, directed a little backwards, below the level of the head, riſing above the hollow of the neck, quadrilateral, convex on the outſide, and exceſſively rough for the attachment of ſtrong tendons, the tendon of the gluteus maximus paſſing over the ſmooth ſurface at the poſterior part; hollow, and of much leſs extent on the inſide, giving attachment above to the tendons of the gemelli, the obturator internus, and the pyramidalis below, and towards the back part to the obturator internus. It has rough and irregular borders; to the anterior is fixed the tendon of the gluteus minimus; to the lower part of the poſterior the quadratus; to the upper the gluteus medius; to the lower the vaſtus externus. The attachments of theſe muſcles are hardly, however, confined to the edges of the trochanter; their tendons are implanted alſo to a greater or leſs extent over the outer ſurface, for which purpoſe its roughneſs, as mentioned above, ſeems particularly deſigned. The little trochanter is placed at the internal and poſterior part of the baſe of the neck, oblong and ſomewhat pyramidal in ſhape, its rough ſummit giving attachment to the united tendon of the pſoas magnus and iliacus. From its baſe we trace two prominent lines proceeding obliquely upwards to the great trochanter, one uniting them in front, the other behind. Theſe, in conjunction with the two trochanters, mark the circumference of the baſis of the neck, and give attachment, more eſpecially the anterior, to the capſular ligament of the hip joint. The body of the thigh bone is convex forwards, and hollowed behind, appearing nearly cylindrical when viewed in front, but almoſt triangular above, and flattened tranſverſely towards the lower end. It has been divided in deſcriptions into three ſurfaces and as many angular lines; theſe characters, however, are not ſtrongly marked; the ſurfaces are univerſally ſmooth, the dividing lines blunt and rounded, if we except the poſterior ridge formed by the union of the internal and external ſurfaces, called with great propriety the linea aſpera, or ſpina femoris. This is formed by two converging rough lines, commencing from each trochanter above; that which proceeds from the trochanter major is the moſt prominent and rough, giving attachment to the gluteus maximus; the pectineus is affixed to the other; and the interſpace is occupied by the quadratus and a portion of the triceps. The double ridge, formed by the approach of the two rough lines, is continued down the bone, when it again divides into two leſs remarkable lines, which terminate in the condyles at the lower extremity. The whole middle of the linea aſpera gives attachment to the triceps; a portion of the biceps has its origin at the lower part, which is continued along the line diverging towards the external condyle; the line going to the internal condyle is ſcarcely obſervable for a little way below the point of bifurcation. Theſe two branches of the linea aſpera leave a triangular interval between them, ſmooth and ſomewhat concave, correſponding to the popliteal veſſels. Beſides the muſcles fixed to different parts of the linea aſpera, the vaſtus externus is attached to almoſt the whole extent of the line, proceeding from the great trochanter to the external condyle; and the vaſtus internus is connected in a ſimilar manner to the line from the little trochanter to the internal condyle. The ſurfaces of the body of the femur are covered by theſe muſcles, and by the crureus, which cover the bone at every point, excepting towards the lower end, and the ſpace intercepted between the bifurcation of the linea aſpera. The nutrient arteries of the body of the bone are found in the courſe of the linea aſpera; the principal one about the point of convergence above.

The lower extremity much exceeds the upper in volume, and preſents two eminences called condyles, the internal and external. They are both convex, project more behind than in front, are ſmooth below for articulation with the tibia, this ſurface being terminated behind by two hollows, which give origin to the heads of the gaſtrocnemius. They diverge behind, leaving a deep notch between them, where the crucial ligaments of the knee joint are fixed; on the front they are joined by a continued articular ſurface, which is hollowed to receive the knee-pan or patella; the edge of the pulley formed by the outer condyle being more elevated than the oppoſite one. The articular ſurface terminates abruptly in the lateral direction, in the perpendicular rough ſides of the condyles; in front it is continued a little way up the bone, ending in a ſlightly prominent edge. The internal condyle gives attachment on the inner ſide to a lateral ligament, and to the tendon of the triceps. The external ſurface of the outer condyle is marked by a depreſſion to which the popliteus is affixed, and by an eminence for the external lateral ligament of the knee. The articular ſurface of this condyle is broader than that of the internal, and not ſo convex, the anterior part being nearly plane; and it is continued much higher up in the front than on the oppoſite ſide. The internal condyle, when the thigh bone is placed perpendicularly, appears to deſcend much lower than the external; but in the natural oblique direction of the femur, the bottom of the two condyles will be found nearly in the ſame horizontal plane, the internal ſtill exceeding a little.

The femur is compact in its ſtructure in the middle part, reticular and ſpongy at the extremities, which are yet cartilaginous at the time of birth. Oſſification commences in the middle of the bone, and it is not till after this has reached the extremities that we obſerve three centres of oſſification above, in the great, the little trochanter, and the middle of the head, and two below, one for each condyle. The cartilages between them and the body of the bone gradually decreaſe in thickneſs, and they become united, the two trochanters the firſt, then the head, and laſt of all the conjoined condyle. It is not till the bone has nearly arrived at its complete and adult form that the line of ſeparation is entirely obliterated. In infancy the neck of the bone is nearer at right angles to the body than at any after period; as the age advances the angle becomes more and more obtuſe in the majority of ſubjects; in ſome few it ſcarcely alters its direction. This alteration, from an horizontal to an oblique line, is a proof among many others how little the functions or growth of the animal body are ſubject to phyſical laws; we ſee the neck of the thigh bone riſing, as it were, in direct oppoſition to the weight of the ſuper-incumbent body. This portion of the femur is alſo proportionally ſhorter than in the adult, and wholly cartilaginous. The body of the bone is ſtraight, inſtead of being curved forwards, as in the adult; and the inferior extremity is comparatively of larger dimenſions. Theſe characters of the infantile bone are loſt as it gradually becomes developed, and acquires its remarkable denſity and firmneſs. The thigh bone is articulated above with the os innominatum, below with the tibia and patella.

The articulation of the femur with the os innominatum, the hip joint.—The ſurface of the cotyloid cavity of the hip bone is lined by an articular cartilage, of which the central parts are thinner than the circumference. It terminates at the edge of the depreſſion obſerved at the inner and lower parts of the cavity, which is filled up by a fatty cellular tiſſue, ſupplied by numerous veſſels. The bony margin of the cavity is completed by a ligament croſſing the notch, and the whole rim of the acetabulum is ſurmounted by a circular ligament, called the cotyloid ligament, which much increaſes its depth. In this round articular cup, or acetabulum, the head of the thigh bone is lodged. The latter is covered by cartilage thinner at the circumference than towards the centre, where it is partially interrupted by the inſertion of a ligament, and accommodated exactly to the oppoſite ſurface of the acetabulum; the cartilaginous head, however, is ſo deep as not to be wholly embraced by this cavity in any poſition; and hence ſome part of its margin always appears expoſed on turning back the enveloping ligament. The contiguous ſurfaces are ſecured in their relations by a very ſtrong capſular ligament, ſupported by fibres from the neighbouring parts, and ſurrounded on all ſides by muſcles; and by an inter-articular ligament. The oppoſed ſurfaces are covered by a ſynovial membrane.

The cotyloid ligament adheres firmly to the edge of the acetabulum at every point, excepting the great notch which it croſſes. It is thick at the border next the bone, thin at the oppoſite prominent margin, broader above, and externally thin in the contrary directions, and partially broader wherever there is any depreſſion in the oſſeous rim, ſo that the unconnected margin of the ligament is exactly plane throughout. It is formed by ligamentous fibres ariſing from the edges of the cavity without, inclining gently towards it in their progreſs, and inſerted again into the ſides of the margin within at a greater or leſs diſtance from their point of origin. Theſe fibres receive an addition above from the curved tendon of the rectus cruris; below they are confounded with the fibres of another ligament, completing the great notch. The latter is formed by two croſs planes of fibres paſſing from one edge to the other; they decuſſate each other in their courſe, one band correſponding to the ſurface of the joint, the other to the edge of the obturator foramen, from the ligament occupying which it partly takes its origin. They leave a vacancy below for the paſſage of veſſels into the joint; towards the brim of the cavity they are continuous with the cotyloid ligament in the manner above-mentioned; they give a partial attachment alſo to the ligamentous capſule. The cotyloid ligament, in conjunction with theſe bands, completes the figure of the acetabulum, and by increaſing its depth ſecures the joint without in any degree diminiſhing the motions of the head of the femur, to the preſſure of which it readily yields. They are both lined towards the joint by the ſynovial membrane, which is continued over the edge of the cotyloid ligament a little way down the oppoſite ſurface, before it is reflected to the capſular ligament. Theſe two laſt are oppoſed to each other in part by its intervention; towards their mutual attachment to the brim of the cavity they are intimately united. Into the articular hollow thus conſtituted, the head of the femur is received, and ſecured by an orbicular and internal ligament.

The capſular ligament of the hip joint, (l. orbiculare, membrana capſularis femoris, Soemm.) extends from the circumference of the acetabulum to the baſe of the neck of the femur. It is fixed to the bony margin of the former from the line of inſertion of the cotyloid ligament, to a ſhort ſpace beyond it, ſo as to ſurround the latter, which projects freely into the joint. Its inſertion extends further beyond the cotyloid ligament in front and on the outer ſide than it does internally, where it may be almoſt ſaid to ariſe from its very edge. From this circular attachment the capſule deſcends, enveloping in its courſe the chief part of the neck of the femur, to the circumference of whoſe baſe it is finally fixed. In front it reaches the oblique line between the trochanters, the linea inter-trochanterica; behind, ſome of its fibres only reach ſo far, the greater number are implanted into the neck between the poſterior oblique line and its middle; above, it is fixed to the root of the great trochanter; below, it extends nearly to the little. The capſular ligament is in general very thick, and of a cloſe and condenſed texture; it is thinneſt internally and behind, thicker externally, and moſt decidedly ſo in front, where it is ſtrengthened by a layer of longitudinal fibres ariſing from the anterior margin of the os innominatum, and from the anterior inferior ſpine, and fixed below to the anterior linea inter-trochanterica. In other parts of the ligament the courſe of the fibres is leſs diſtinctly marked; from the margin of the acetabulum they follow different directions, decuſſating each other, and leaving occaſional intervals, more eſpecially below, through which veſſels paſs to the ſynovial membrane. This laſt is occaſionally expoſed and bare on the ſide next the obturator foramen. The capſular ligament is covered in front by the rectus cruris, pſoas magnus, and iliacus internus, a ſynovial burſa lying between them; on the internal ſide, by the obturator externus and pectineus; behind, by the quadratus femoris, the gemelli, the tendon of the obturator internus, and the pyramidalis; above and without, by the gluteus minimus, which is more cloſely connected with it than any other of theſe muſcles.

The interior, or round ligament, (ligamentum teres, internum) is entitled to almoſt any name rather than round; it is flattened, and of a triangular figure, the baſe towards the acetabulum, the ſummit next the head of the femur. It is fixed at one end to the extremities or corners of the great notch of the cotyloid cavity, and to the poſterior edge of the tranſverſe ligament occupying the vacancy; from thence it mounts obliquely backwards, and is attached to the depreſſion noticed towards the centre of the head of the thigh bone. It appears as if compoſed of two bands of fibres, one ariſing from the ſuperior, the other from the inferior extremity of the great cotyloid notch, which approach each other towards their oppoſite inſertion. The upper of theſe is by far the weakeſt; in many caſes it appears only as a duplicature of the ſynovial membrane, encloſing only a ſmall number of ligamentous fibres. It muſt reſtrain the head of the femur from quitting the cavity upwards and outwards, and muſt be partially, if not entirely, ruptured in the luxations in thoſe directions; in the diſplacement towards the obturator foramen it would not apparently ſuffer much injury.

The ſynovial membrane lines the cotyloid cavity, is ſpread over the fatty cellular tiſſue, occupying the ſinus at its bottom, is reflected from thence over the internal ligament, which it wholly encaſes, adhering to it more or leſs intimately in different parts: it covers the articular cartilage of the head of the femur, is continued over the perioſteum of the neck, which appears through it as if formed of parallel fibres; at the baſe of the neck it turns back over the inner ſurface of the capſular ligament, lines it to its attachment round the brim of the acetabulum, and from thence paſſes over the cotyloid ligament. The hip joint is very much ſtrengthened by the ſurrounding muſcles, eſpecially by thoſe which immediately cover it.

The motions which take place in the hip joint reſemble thoſe in the ſhoulder; they are, however, with the exception of rotation, leſs extenſive, owing to the immobility of the cotyloid cavity, its great depth, and the comparative tightneſs of its capſular ligament. The femur can be bent on the hip bone, extended, brought nearer to, or removed further from, the meſial plane, moved between theſe directions, or carried round in a circular direction (*circumduction*), and rolled inwards and outwards. In the moſt common poſition, with the thigh in the ſame line as the body, the ſummit of the great trochanter, which can be always felt externally under the integuments, is in the ſame horizontal line with the ſpine of the pubis, and about the middle of an oblique line extended between the ſuperior anterior ſpine of the ilium, and the tuberoſity of the iſchium. By a previous knowledge of the relative poſition of this eminence to points which can be eaſily felt, we ſhall be competent to decide on any accidental diſplacement, as well as to follow the alteration of poſition in the different motions of the femur.

When the thigh is bent, the head rolls in the acetabulum in the axis of the neck, the ſummit of the trochanter recedes from the ſpine of the ilium, and approaches the tuber of the iſchium, and the lower end of the bone is advanced. In moderate flexion there is but little alteration in the relations of the articular ſurfaces; when carried to its greateſt degree, a portion of the head of the femur quits the acetabulum, and reſts on the poſterior part of the capſular ligament, which undergoes conſiderable diſtenſion. Extenſion of the thigh is the replacement of the limb in its former ſtate, from the poſition of flexion. The very cloſe manner in which the head of the bone is covered in front by the ſtrong ligamentous fibres, which proceed from the anterior and inferior ſpine of the ilium, and the neighbouring anterior portion of the cotyloid line, entirely prevent us from carrying the limb backwards beyond a perpendicular line drawn from the pelvis downwards, if the latter part be preſerved immoveable. The degree of motion in this direction, if it exiſt at all, is very trifling, ſuppoſing the trunk to be erect, and the pelvis fixed; the apparent freedom of motion in the direction of extenſion ariſes from the pelvis being ordinarily moved in the oppoſite direction.

In abduction, or removing the thigh from its fellow, the great trochanter riſes towards the foſſa of the ilium, which it touches, if the motion be continued as far as poſſible, and thereby limits the extent of that motion. The internal ſurface of the head abandons the acetabulum, while the external ſinks deeper into it; the capſular ligament is made very tenſe on the inner ſide, where it ſupports the head and oppoſes its tendency to any diſplacement in that direction. In adduction nothing remarkable occurs; it is merely the return of the thigh from the laſt poſition to its natural one; the limb may, however, be carried, in this direction, acroſs the oppoſite one. Beſides theſe four motions in oppoſite lines, it will be readily underſtood that the femur can be moved through all of the intermediate points. Circumduction is not ſo free as in the ſhoulder joint, as may be gathered from the preceding obſervations: rotation is, on the contrary, leſs confined, on account of the length and obliquity of the neck of the femur, ſo ſtrikingly different from that of the humerus. In the latter rotation is nearly in the axis of the bone, on account of the extreme ſhortneſs of the neck; in the femur, where the axis of the bone is ſo far removed from the centre of motion, this motion paſſes round a line extended from the upper part of the head to the middle point or interval between the condyles. In rotation inwards, which is more confined than that outwards, the great trochanter deſcribes the arc of a circle from behind forwards, and the head of the bone is buried deeper in the cavity; the motion of the trochanter is more ſenſible and more extenſive as the neck is proportionally longer. In rolling the thigh outwards the great trochanter ſinks under the muſcles, and the head of the bone diſtends the capſule ſomewhat in front. In its moſt natural poſition the thigh is turned a little outwards, which contributes, with the direction given to the foot by the conſtruction of the ankle joint, to point the toes moderately outwards. As the leg and foot neceſſarily follow the rolling motions of the thigh, and more perfectly ſo when the leg is extended on the latter, it will be ſeen that the rotation of this bone inwards and outwards will imply a correſponding alteration in the poſition of the foot; and the great power we enjoy of turning the toes outwards, and the narrow limits to which we are confined in directing them inwards, will be found to reſult from the difference obſerved in the powers of rotation of the thigh.

The motions of the hip bone on the thigh, when the latter is the fixed point, will require no particular detail after the preceding remarks. It is ſufficient to ſay they may be made in every direction, and with tolerable facility, particularly lateral inclination, in which one hip bone is lowered, and the oppoſite one elevated, and rotation; motions executed with promptneſs and to a great extent in the *pirouettes* of our ſtage dancers. We ſhall have occaſion to ſpeak at length of the flexion and extenſion of the hip bones on the thigh, when we examine the mechaniſm of the whole in the attitude of ſtanding.

The leg—is the part of the lower extremity placed between the thigh and the foot; the bones which it contains are the tibia, the fibula, and the patella.

The tibia, the largeſt of the three, alone ſupports the weight placed on the leg from above; it comes next to the femur in ſize, is larger above than below, nearly triangular throughout, divided into an upper, femoral extremity, or head, a middle part or body, and a lower or tarſal extremity.

The upper extremity is nearly oval, with the long diameter tranſverſe, large, and ſpreading.

The vertex or top preſents two articular hollows or ſinuſes; of which the internal is oblong from before backwards, and deeper than the external, which is nearly circular. They correſpond to the condyles of the femur by the intervention of moveable cartilages; and are divided from each other by a middle eminence, terminating in a rough depreſſion before and behind, which completes the ſeparation. This protuberance, placed neareſt to the poſterior edge of the head, is not much elevated; it ſlopes into the articular ſurfaces at the baſe, and is bifid at the ſummit, with a rough groove in the interval. The rough depreſſion in front is larger than that behind; they both give attachment to the ſemi-lunar inter-articular cartilages of the knee, and to the crucial ligaments of the joint. In front of the upper extremity is a broad, flat, triangular ſurface, with the baſe upwards, correſponding to the ligament of the patella. The lateral parts have been called the tuberoſities; they project conſiderably by a convex edge, ſeparated in front by the flat ſpace juſt mentioned, behind by a notch varying much in depth. The internal protuberance is the largeſt, and is marked by the attachment of the ſemi-membranoſus behind, the external preſents in the ſame aſpect a rounded articular ſurface inclined downwards, for connection with the fibula.

The body of the tibia is ſlightly curved outwards above, and inwards below, diminiſhing in bulk as we trace it from the upper extremity till about one-third from its lower end, from which point its ſize gradually increaſes again downwards. It is of a priſmatic form, with ſtrongly marked edges. The anterior of theſe, the criſta or ſpine, commences above at a rough eminence, called the anterior tuberoſity of the tibia, into which the inferior ligament of the patella is fixed in front, and the tendons of the ſartorius, gracilis, and ſemi-tendinoſus internally; it is ſharp above and in the middle, in the latter of which portions it projects a little, and becomes inſenſibly loſt below; it forms by its courſe a waving line, which gives attachment to the aponeuroſis enveloping the muſcles of the leg. The internal edge is flattened above, and more angular below; in the firſt portion it gives attachment to the popliteus, for the lower two-thirds to the long flexor of the toes. To the external ridge, the leaſt prominent of the three, the interoſſeous ligament is fixed; below it bifurcates and is continued into the edges of the articular cavity, which receives the lower end of the fibula. Of the ſurfaces between theſe edges, the internal or the ſhin is the largeſt; ſmooth, ſlightly convex above, and covered by the tendons of the ſartorius, gracilis, and ſemi-tendinoſus; throughout the reſt of its extent it lies immediately under the ſkin. The outer ſurface is hollowed longitudinally above, and convex below, where it turns a little forward; its upper half is covered by the tibialis anticus, to which it gives attachment, and lower down the tendon of this muſcle, with thoſe of the extenſor of the great toe, and the common long extenſor of the toes, paſs over it. The poſterior ſurface is croſſed obliquely by a line paſſing downwards and inwards from the articular ſurface, at the back of the external tuberoſity; above this the popliteus is attached; below, the tibialis poſticus, and long flexor of the toes; to the line itſelf theſe muſcles are fixed, as alſo the ſoleus. It is towards the upper end of the poſterior ſurface that we find the hole which gives paſſage to the nutrient veſſels.

The lower extremity is much leſs in volume than the femoral or upper; it is nearly quadrilateral with an articular cavity of the ſame form at the bottom, which reſts on the foot. Of the four ſides, the anterior and poſterior are ſtraight, tranſverſely and nearly parallel, giving attachment at their edges to ligamentous fibres; the latter preſents alſo a groove for the paſſage of the long flexor of the great toe. The internal is prolonged downwards below the level of the others, forming a broad and ſtrong proceſs, called the malleolus internus. This eminence does not correſpond exactly to the inner tuberoſity of the femoral end, but is ſituated a little more forwards from the ſlightly twiſted form of the bone. The circumference of its anterior and loweſt parts gives attachment to ligaments; the poſterior has a broad and ſuperficial hollow, over which paſs the tendons of the tibialis anticus, and the long flexor of the toes; the inner ſurface is convex, and covered by the ſkin, the external is ſmooth, preſenting a vertical articular ſurface, joining above the large articular cavity, the depth of which it conſiderably increaſes. On the outer ſide of the tarſal extremity is a triangular hollow with the ſummit upwards, ſmooth below, and covered by cartilage, where it receives the fibula, rough above for the attachment of ſtrong and ſhort ligamentous fibres, which ſecure the connection: the edges of the cavity are continued above into the external ſpine of the body of the bone, and give attachment to ligaments which paſs to the fibula. The articular ſurface at the bottom is a little concave, quadrilateral, narroweſt and deepeſt towards the inner ſide, croſſed antero-poſteriorly by a broad gently riſing eminence; it correſponds to the upper ſurface of the aſtragalus, the higheſt of the bones of the tarſus.

The ſtructure and formation of the tibia reſemble thoſe of the other long bones. At birth the extremities are cartilaginous, and are not completely oſſified and united to the body till a late period; the bony ſpines in the latter are already very prominent, and better marked than in any other bone. The tibia is articulated with the femur, the fibula, and aſtragalus.

The patella, rotula, or knee-pan (knieſcheibe, Germ.) is ſituated in front of the knee-joint, or articulation between the femur and tibia, varying as the leg is bent or extended, in its relative poſition with regard to the femur. It is flattened, of a triangular form, with the baſe upwards, the upper angles rounded, the lower more acute. The anterior ſurface is convex, pierced by numerous longitudinal openings, covered by a tendinous expanſion from the extenſors of the leg, which is partially attached to it, and by the ſkin. The poſterior articular ſurface is oblong, tranſverſely divided by a blunt elevated line, paſſing rather obliquely from the upper edge to the lower angle, into two differently inclined concave faces, of which the external is the largeſt and deepeſt; they both correſpond to the condyles of the femur on which they play. It is terminated below by a rough depreſſion, into which a portion of the ligament of this bone is fixed. Of its circumference, the upper edge is thick, and gives attachment to the tendon of the extenſors, the lateral borders ſlightly convex, to the common aponeuroſis of theſe muſcles. In the lower angle the ſtrong anterior ligament which connects the patella to the tuber in front of the tibia is firmly implanted.

The ſubſtance of the patella is ſpongy in the middle, covered by a thin cruſt of compact bone. It is formed in the thickneſs of the tendon of the extenſors, and always preſerves the appearance of longitudinal fibres. It is not till ſome years after birth that bony matter is depoſited in room of the cartilaginous ſubſtance at firſt obſervable, and it is a later period ſtill before it is fully developed. The patella is articulated with the femur, and connected with the tibia by means of a ligament, of which we ſhall ſpeak below.

The knee joint, or articulation of the femur with the tibia and patella.—This joint, one of the moſt complicated in the body, reſults from the contact of the condyles of the thigh bone with the head of the tibia and the poſterior ſurface of the patella. The firſt of theſe, as well as the articular pulley formed by their union in front, are covered by cartilage, which is thicker in the middle of the condyles than at their circumference; the cartilage covering the patella is particularly thick, it is thinner on the hollows of the tibia, particularly in their centres. The forms of the articular ſurfaces of the femur are accommodated to thoſe of the patella and tibia; but in the latter caſe the correſpondence is further maintained by means of two inter-articular ſemilunar fibro-cartilages, interpoſed between the femur and tibia in ſuch a manner, that a ſmall portion only of the latter bone comes into actual contact with the condyles of the former. The relations between theſe parts are ſecured by muſcles, and their tendons, by the ligament of the patella, two lateral, and the ſame number of crucial or oblique ligaments, a poſterior ligament, and by a ſynovial membrane ſpread over the whole.

The ligament of the patella, which may be regarded as the termination of the tendons of the extenſor muſcles, conſiſts of a very ſtrong flat band of fibres attached above to the lower angle of that bone, and to the depreſſion on its poſterior ſurface, from which points it extends about two inches in length, and half as much in breadth to the anterior tuberoſity of the tibia. It is covered in front by the ſkin and an aponeurotic expanſion. The poſterior ſurface correſponds above to ſome fat and cellular tiſſue lying betwixt it and the ſynovial membrane, below to a ſmall ſynovial capſule placed between it and the tibia, a ſmooth portion of which it covers, juſt above the inſertion of the ligament. The edges are continuous, with an aponeuroſis proceeding laterally to the tibia. It is compoſed of parallel, ſhining, tendinous fibres, of which the anterior or moſt ſuperficial are continued in front of the patella to be identified with thoſe of the immediate tendons of the extenſors. It is exceedingly ſtrong, and capable of reſiſting the ſtrongeſt efforts of theſe muſcles.

The internal lateral ligament is flat and thin, attached above to the internal condyle of the femur, it becomes broader as it deſcends, part of its fibres is inſerted into the edge of the internal ſemi-lunar cartilage, and into the edge of the head of the tibia, the greater portion contracted in breadth is continued further down, and becomes fixed at the commencement of the body of the bone to the internal edge, where it joins the aponeurotic inſertion of the popliteus. It is covered by an aponeuroſis deſcending from the faſcia lata of the thigh, and below by the tendons of the ſartorius, the gracilis, and ſemi-tendinoſus: it lies over the ſynovial membrane, the internal ſemi-lunar cartilage, and a ſmall part of the tibia. The external lateral ligament is placed between the external condyle of the femur, and the fibula, in the form of a long, round, ſhining cord, covered nearly throughout by the tendons of the biceps. Immediately under it are the inferior articular veſſels. It is fixed to the condyle above the attachment of the tendon of the popliteus, and rather behind it; to the fibula on the outſide of its upper extremity, adhering to the outer ſemi-lunar cartilage in its paſſage. The poſterior ligament is nothing but a tendinous expanſion given off from the tendon of the ſemi-membranoſus, which mounts obliquely upwards

wards and outwards behind the crucial ligaments, from which it is ſeparated by cellular tiſſue and the middle articular veſſels. It is attached above to the external condyle, and is confounded with the tendon of the outer head of the gaſtrocnemius. Independent of this band, which is very irregular in its form and ſize, we find other fibrous parcels croſſing in different directions above it.

The crucial ligaments are more deeply ſeated, but may ſtill be conſidered as external to the joint as they are covered only in front, and on the ſides by the ſynovial membrane, and are really without the ſac which it forms. They are ſtrong fibrous bands croſſing each other in their courſe, from which they derive their name. The anterior paſſes from the poſterior and upper part of the hollow between the condyles, and from the interior ſide of the external condyle; obliquely downwards and forwards, narrowing as it deſcends, to be fixed in the rough ſurface, in front of the ſpine at the head of the tibia, behind the attachment of the internal ſemi-lunar cartilage, and on the inſide of the external, being partially united to both. The poſterior crucial ligament is attached above to the anterior part of the ſinus between the condyles, and the outer-ſide of the internal condyle. It deſcends backwards and inwards, becomes broader, and divides into two pretty diſtinct bands, of which the largeſt is inſerted into the depreſſion behind the ſpine, the other joins the external ſemi-lunar cartilage. Theſe two ligaments are ſeparated from each other by cellular tiſſue, and by the ſame means from the poſterior ligament behind; they adhere firmly to the ſynovial membrane, inveſting them on the anterior and lateral ſurfaces.

The ſemi-lunar cartilages, as they are termed, lie on the articular ſurfaces of the tibia, between them and the correſponding condyles, occupying only the circumference, the femur and tibia touching in the centre of each. They are thick at the convex margin, and become gradually thinner, terminating in a delicate concave edge, increaſing thereby the depth of the cavities which receive the gibbous condyles of the femur. The internal is broadeſt behind, the external in front; the firſt repreſents a portion of an oval, of which the ſhort diameter is tranſverſe; the latter forms nearly a circle, correſponding, in this reſpect, to the figure of the two articular ſurfaces of the tibia. The upper ſurface of each cartilage is concave, accommodated to the convexity of the condyles, the lower is nearly flat. The convex margins are united to the ligaments which croſs them in their courſe, eſpecially to the lateral; that of the external has an oblique depreſſion in it behind, where it is contiguous but not adherent to the tendon of the popliteus. The concave edges are free, thin, and ſharp. The anterior extremity of the internal cartilage paſſes in front of the anterior crucial ligament, and is inſerted on the outer ſide of the depreſſion which gives attachment to it; the poſterior is attached behind the ſpine, before the inſertion of the poſterior crucial ligament. The anterior extremity of the external ſemi-lunar cartilage is faſtened to the depreſſion in front of the ſpine, but much behind the attachment of the internal, and united in part with the anterior crucial ligament; behind it is implanted into the poſterior depreſſion, and is connected with a portion of the poſterior crucial ligament. We have called theſe cartilages, not to depart too much from eſtabliſhed language, though they are of a fibrous texture. They are formed of curved concentric fibres, which are particularly evident at their extremities and convex margins, leſs ſo in the middle, where they are more analogous in their appearance to cartilage. They are ſometimes immediately joined by a ſhort tranſverſe ligament, continued from the convex borders in front. The internal appears more fixed in its ſituation than the external, which has a gliding motion backwards and forwards on the tibia.

The ſynovial membrane, if we trace it from above, is reflected from the condyles of the femur, ſome way above the termination of the cartilage to the circumference of the patella. In this part it is looſe, covered above by looſe fat and by the cruræus, to the tendon of which it adheres moſt firmly, and laterally by an aponeurotic expanſion, from the extenſors paſſing from the edges of the patella to the tibia and femur. After lining the poſterior ſurface of the patella, it paſſes on to the upper edge of the tibia in front, lying under the ligament of the former bone, and a large quantity of fat and cellular tiſſue placed underneath it, and keeping them at a conſiderable diſtance. From this part a duplicature of it paſſes backwards through the joint, and is attached to the anterior and external part of the ſinus between the condyles. It has been called the ligamentum alare by Weitbrecht, or l. mucoſum, ſeu adipoſum; all names equally unapplicable to it. Laterally, alſo, it deſcends towards the tibia, inveſting the upper ſurfaces, and concave edge, and the under ſurfaces of the ſemi-lunar cartilages; after which it is continued downwards, covers the articular cartilages at the head of the bone, and is reflected upwards over the crucial ligaments in the middle, lining behind the tendons of the gaſtrocnemius on their anterior ſurface, and enveloping the tendon of the popliteus. It thus reaches the condyles behind, to the edges of which it is attached, leaving the ſinus between them without the bag, and paſſes over the cartilages to the point from which we ſet out. It is covered in front by the extenſors and their tendon; by their aponeuroſis laterally, as alſo on the inſide by the tendons of the ſartorius, gracilis, and ſemi-tendinoſus, and by the internal lateral ligament with which it is in contact; on the outſide by the tendon of the biceps and the external lateral ligament, behind by the ſemi-membranoſus and its lateral tendon, by the gaſtrocnemius and popliteus. After all, we ſhould have a very imperfect idea of the knee joint, if we conſidered it in this abſtract ſtate. It is moſt ſtrongly ſupported by the muſcular powers attached to the tendons we have mentioned, the latter being numerous, and of great ſtrength, and the muſcles maſſy and exceedingly powerful, ſecuring moſt effectually, when in action, the relations of the oppoſite bones.

The motions of the leg on the thigh—are thoſe of flexion, extenſion, and under particular circumſtances of rotation. In flexion, the tibia and ſemi-lunar cartilages glide backwards on the condyles of the femur; the patella quits the articular pulley, and deſcends in front of the joint, ſo as to be oppoſite to the ſinus between the condyles: the tendon of the extenſors occupies its place, and is much diſtended if the flexion be carried far back, as is alſo the ligament of the patella; and the crucial and oblique ligaments, as well as the poſterior, are relaxed. In extenſion, the tibia glides forwards again, and the ſemi-lunar cartilages are brought oppoſite to the inferior inſtead of the poſterior ſurfaces of the condyles, which, in this poſition, reſt againſt the heads of the gaſtrocnemius; the patella mounts again, and, in complete extenſion, if the muſcles are in action, paſſes up a little way above the articular pulley; if the muſcles are quieſcent, the tendon of the patella is relaxed; this bone is looſe and may be moved in all directions; the poſterior crucial and lateral ligaments are ſtretched, and prevent this motion from being carried beyond the point which brings the femur and tibia in the ſame line. The great ſtrength of the crucial ligaments, which are eſſentially diſtended at this time, is a powerful obſtacle to the luxation, which would throw the head of the tibia backward. When the leg is near the middle ſtate, between complete flexion and extenſion, it can be rotated ſlightly inwards and outwards; a motion, of which the foot neceſſarily partakes, and which carries the toes in correſponding directions. In rotation the articular ſurfaces of the tibia glide in oppoſite curves in the rounded ſurfaces of the condyles; not, however, in equal degrees, the moſt evident motion occurring on the outer condyle. In rotation inwards the poſterior crucial ligament is brought to croſs the anterior more directly, and is much tightened, ſo as effectually to limit it. In rotation outwards, which, on account of the diſpoſition of theſe ligaments, is more extenſive, we find them ſcarcely affected. In both caſes the lateral ligaments are rendered tenſe; the ſemi-lunar cartilages undergo little change of poſition, excepting that in rotation inwards, the external one, from its connection with the poſterior crucial ligament, is drawn a little aſide. When the leg is bent, the motions by which the toes are carried alternately inwards or outwards take place in the knee joint; when it is extended, they are effected in the hip, and depend on the rotation of the femur. The patella favours extenſion, by removing the power further from the centre of motion, beſides which it glides more readily over the pulley of the femur, than a flexible tendon could have done, and protects materially the front of the joint in flexion, for inſtance in kneeling. It ſcarcely moves in rotation inwards or outwards.

The fibula—is placed on the external ſide of the leg, obliquely with regard to the tibia, being behind it above, and immediately on the outſide below. It is a ſlender bone, nearly equal in length to the tibia, but very much ſmaller, divided into an upper or tibial, or lower or tarſal extremity, and a middle portion or body.

The upper extremity is very irregular; we remark in it above, and a little on the inſide, an oblique, ſlightly hollowed, articular ſurface, correſponding to one on the outer tuberoſity of the head of the tibia. In every other aſpect the ſurface is rough and unequal, giving attachment to ligaments which connect it with the tibia, to the external lateral ligament of the knee, and to the tendon of the biceps.

The body of the fibula is of an irregular priſmatic figure, ſomewhat twiſted, and curved a little, ſo as to approach nearer the tibia in the middle of the three angles, the anterior riſes gradually from above, is ſharp and prominent in the middle, and bifurcates below, where it is covered only by the ſkin. It gives origin, in the greateſt part of its extent, to an aponeuroſis, which ſeparates the peronei muſcles from the extenſor communis of the toes. The external edge is ſpiral in its courſe, running backwards as it deſcends. It gives attachment to an aponeuroſis, which divides the peronei from the long flexor of the great toe and the ſoleus. The internal edge becomes anterior as it deſcends; it is very prominent in the middle, and gradually loſt above and below. The upper two-thirds give origin to the flexor of the great toe, and the tibialis poſticus, the lower third to the interoſſeous ligament. Of the ſurfaces between theſe borders, the external alters its aſpect, becoming poſterior below; it is covered by the peronei, which are fixed to the two upper thirds. The internal ſurface looks rather backwards above, and forwards below; it is divided into two unequal portions by a ſpine extending from the upper part of the anterior angle to the lower part of the internal angle, and which gives attachment to the interoſſeous ligament. Of theſe two planes the anterior is covered by, and gives origin to, the extenſors of the great and of the other toes, and to the peroneus tertius; the poſterior, which is hollowed longitudinally, to the tibialis poſticus. The direction of this ſpine varies very conſiderably, as alſo its length. The poſterior face is inclined outwards above, where the ſoleus has its attachment; below it turns inwards, giving attachment by nearly its lower two-thirds to the long flexor of the great toe. About the middle is the opening for the nutrient artery directed longitudinally downwards. It widens towards the lower extremity, where it terminates in a rough convex ſurface, connected with the tibia.

The lower or tarſal end of the fibula is oblong, flattened tranſverſely, thicker behind than in front; it forms the outer malleolus, which deſcends rather lower, and is more pointed than the inner. The external ſurface is convex, and covered only by ſkin; the internal preſents, at its anterior part, a ſmooth articular ſurface convex from above downwards, articulated with the external ſide of the aſtragalus, and behind this a rough depreſſion for ligamentous attachments. The poſterior border has in it a ſuperficial groove for the paſſage of the peronei; the anterior, as well as the angle below, give attachment to ligaments.

The fibula is in ſtructure like the other long bones. It is formed from three points of oſſification, one for the body and one for each extremity. The latter are ſtill cartilaginous at birth.

The articulation between the tibia and fibula—is by actual contact at the two extremities, and by means of an interoſſeous ligament in the intervening ſpace. The ſuperior articulation reſults from the contact of two flat cartilaginous ſurfaces, ſecured by ligaments in front and behind, and covered by ſynovial membrane. The anterior ligament paſſes from the fore part of the upper end of the fibula to the anterior part of the external tuberoſity of the tibia. The fibres are tranſverſe, the ſuperior ones the longeſt, and divided into ſeveral parcels, with intervening cellular tiſſue. It is ſtrengthened by a portion of the tendon of the biceps, which embraces the external lateral ligament of the knee, and paſſes over this anterior ligament before it is fixed to the tibia. The poſterior ligament is alſo tranſverſe, but not ſo ſtrong, or ſo well marked as the preceding; it is continued above with ſome ligamentous fibres found in the back of the knee-joint; it is covered by the popliteus. Beſides theſe two ligaments, we find a few other ſcattered bands below, which help to ſecure the articulation. The ſynovial membrane lines theſe ligaments, and the cartilaginous ſurfaces; it is ſeparated from the tendon of the biceps by cellular tiſſue, and is contiguous behind to the ſynovial membrane of the knee. The middle connection is preſerved by means of an interoſſeous ligament, analogous to the one we have deſcribed in the fore-arm. It is thin, compoſed of parallel fibres deſcending obliquely from the external edge of the tibia to the ridge dividing the internal ſurface of the fibula, and below to the internal edge of this bone. It is broadeſt at the upper part, and terminates in a point beneath, where the bones begin to touch each other. It is pierced by many openings for the paſſage of veſſels; of theſe the moſt remarkable are, one above, near the edge of the fibula, for the paſſage of the anterior tibial veſſels; and another below for a branch from the peroneal artery. The anterior ſurface ſerves for attachment to the tibialis anticus, the extenſors of the great and other toes, and to the peroneus tertius, and ſupports the anterior tibial veſſels. To the poſterior ſurface the tibialis poſticus and long flexor of the great toe are fixed. The inferior articulation is compoſed of the contact of two cartilaginous ſurfaces below, a convex for the fibula, and a correſponding concave one for the tibia, lined by a continuation of the ſynovial membrane from the ankle joint. The relations are ſecured by ligaments before, behind, and between the bones. The anterior ligament is broad, attached to the anterior edge of the tarſal end of the fibula; in croſsing to the tibia it mounts a little upwards, widening in its progreſs, its fibres divided by intervals filled with cellular tiſſue, the ſuperior the longeſt, and is fixed to the neighbouring parts of the tibia. It is covered by the peroneus tertius, aponeuroſis of the leg and the ſhin; its lower end is confounded with ligamentous fibres paſſing from the fibula to the aſtragalus. The poſterior ligament reſembles it in direction, but it is not ſo large, and the lowermoſt fibres are the longeſt. It paſſes immediately from the poſterior part of this end of the fibula to be fixed to the tibia behind the cavity which lodges that bone, is confounded with the ſurrounding ligaments below, covered behind by the two lateral peronei muſcles. In addition to theſe ligaments we obſerve, between the oppoſite ſurfaces of the two bones, juſt above their cartilaginous contact, a fibrous ſubſtance paſſing from one to the other, occupying a conſiderable ſpace, interrupted here and there by cellular tiſſue, and continuous above with the interoſſeous ligament. It materially ſecures the articulation.

The motions of the fibula on the tibia are exceſſively limited, very different in this reſpect from thoſe between the bones of the fore-arm. The upper end of the fibula may glide a little backwards and forwards; the lower is nearly motionleſs from the diſpoſition of the ligaments, a ſtructure neceſſary for the ſtability of the articulation of the leg with the foot, as reſiſting the tendency to lateral diſplacement.

The foot—forms the laſt diviſion of the lower extremity; it has ſome characters in common with the hand, but is diſtinguiſhed from it in a remarkable manner by its great depth and firmneſs, by the preponderance of its ſolid over its moveable parts, the reverſe of which is ſo ſtrikingly ſeen in the hand. It varies much in ſize, in general is proportionably ſmaller in the female than in the male, is elongated in form, broad and flat anteriorly, thick and narrower behind. It is convex on the upper ſurface, which is called the back of the foot, concave on the lower, called the ſole, thin on the outer edge, deeper and longer internally, with a projection behind, named the heel, and terminated by the points of the toes in front. We divide it, as we did the hand, into three portions; the tarſus behind, the metatarſus in the middle, and the toes before.

The tarſus (oberfuſs, Germ.) forms about the poſterior half of the foot; it is compoſed of ſeven bones, *viz.* the aſtragalus, the os calcis, naviculare, cuboides, and three cuneiform bones.

The aſtragalus, (talus of Albinus,) occupies the upper part of the tarſus, riſing far above the level of the other bones; it is of a very irregular form, convex above, hollowed below, flattened at the ſides, and running out into a ſtrong proceſs before, termed the cervix or neck of the bone. It is placed faſt between the two bones of the leg, the heel bone, and the os naviculare. On the upper ſurface, anteriorly, is a rough, tranſverſe depreſſion, forming part of what has been called the neck of the bone, for inſertion of ligaments; behind this is a large articular ſurface, broader before than behind, convex in thoſe directions, rather concave from ſide to ſide, ſo as to form a ſuperficial pulley, ſuited to the oppoſite ſurface of the tibia. Below we have two articular ſurfaces, which reſt on the os calcis, ſeparated by a deep groove, running obliquely from within outwards, widening much in its courſe, and rough for ligamentous attachments. The poſterior articular ſurface, which is external, is the largeſt, concave, and oblong obliquely; the anterior is ſmall, oval, and nearly flat. The poſterior ſide is narrowed horizontally, and preſents the commencement of an oblique groove, in which the tendon of the long flexor of the great toe glides. In front is a convex rounded articular ſurface, which has been called the head of the bone; it reſts againſt the os naviculare, and by a ſmall ſurface on the os calcis. On the outſide a triangular articular ſurface, concave vertically, correſponding to the lower end of the fibula. On the inſide another articular ſurface, flat, elongated horizontally, adapted to the deſcending malleolus internus; below this a rough irregular ſurface for ligaments. Theſe two articular ſurfaces are continuous with that on the upper ſurface, and form part of the ankle joint. It is developed from two points of oſſification, which are juſt appearing at birth.

The os calcis (calcaneus of Albinus,) is ſituated at the poſterior part of the tarſus, where it forms the heel. It is the largeſt of the ſeven bones; its greateſt extent is from behind forwards, its next is in the depth, and it is narroweſt tranſverſely. On the ſuperior ſurface we obſerve poſteriorly a concave part occupied by the fat and cellular tiſſue in front of the tendo Achillis; next we have a large, convex, oblique articular face, adapted to one in the aſtragalus; on the inſide of this a groove, which divides it from another ſmaller oval, flat, articular facet, correſponding alſo to the aſtragalus. This laſt is placed on a lateral proceſs of the bone, ("ſuſtentaculum cervicis tali, Alb.") and is rather anterior to the firſt. It is ſometimes continuous with another ſmall articular ſurface in front of it, though generally ſeparated by a narrow groove. The reſt of the upper ſurface is flat and rough for ligaments. The under ſurface is long, much contracted tranſverſely, terminated behind by two tubercles which give attachment to ſome muſcles of the toes; the internal is the largeſt. There are alſo other eminences further in front to which ligaments are fixed. The poſterior ſurface is bulging and convex, and forms properly the heel; at the upper part it is ſmooth, where it is ſeparated from the tendo Achillis by a ſynovial *burſa*, and rough below for its inſertion. The anterior ſurface is the ſmalleſt of the whole; it is articulated with the os cuboides, and is ſlightly concave. The outſide is flat, much broader behind than before, and marked by two ſuperficial grooves for the long and ſhort peronei muſcles. The inſide is large and hollowed deeply, to lodge the nerves and veſſels going to the ſole of the foot, and alſo the tendons of the tibialis poſticus, the long extenſor of the toes, and the long extenſor of the great toe, which plays in a peculiar groove obſerved at its upper part. The muſculus acceſſorius has its origin from this ſurface, towards the back part. The os calcis is formed from two points of oſſification, which are viſible at birth. The two bones we have been deſcribing have been conſidered as the firſt row of tarſal bones; the remaining five as the ſecond.

The os naviculare is ſituated in the middle of the tarſus, of an oval figure, with its longeſt diameter tranſverſe; its circumference is rough for ligamentous attachments; broad and convex above, concave below, pointed and projecting internally where the tibialis poſticus is inſerted, and narrowed on the outer ſide, on which we generally find a flat articular facet oppoſed to the cuboides. The anterior ſurface is convex, divided into three articular planes for the three cuneiform bones; of theſe the internal is broadeſt below, and the two external above. The poſterior ſurface is concave, articulated with the aſtragalus.

The os cuboides, (cubiforme, Alb.) is placed at the external and anterior part of the tarſus, and reſembles ſomewhat a cube in figure. Above is a rough, ſlightly convex ſurface, with four unequal ſides; below poſteriorly an eminence for ligaments, a ſuperficial hollow, and a more marked protuberance for the ſame purpoſe, in front of which is a deep groove, which gives paſſage to the tendon of the peroneus longus, as it croſſes the foot. Anteriorly an oblique articular ſurface nearly plane, ſupporting the two outer metatarſal bones. Behind a concave ſmooth ſurface, ſtill more oblique, articulated with the os calcis. Externally, a narrow border, in which we obſerve the commencement of the groove for the tendon of the peroneus longus. Internally, a ſmall articular facet behind, in contact with the os naviculare; a larger one in the middle for the third cuneiform bone; the reſt of the ſurface is rough for ligaments.

The firſt cuneiform bone (majus ſive internum) lies at the inner and anterior part of the tarſus, and is the largeſt of the three; it is deeper than it is broad, with the baſe of the wedge below, and the narrower border upwards, of a rhomboid figure viewed laterally. The upper ſide is oblique, and gives attachment to ligaments; the inferior is convex, and gives attachment before to the tibialis anticus, behind to a part of the tibialis poſticus, as well as to ligaments. The poſterior ſurface, articulated with the naviculare, is concave and pointed above; the anterior, by which it reſts on the firſt metatarſal bone, is longer, and of an oblong, or rather ſemi-lunar figure. Internally, it is convex, rough, and ſub-cutaneous; externally concave, with a ſmall articular facet near the upper edge, in contact with the ſecond bone of the metatarſus, and another near the poſterior edge, which touches the following bone.

The ſecond cuneiform bone (minus ſive medium) is the ſmalleſt of the three, and of all the bones of the tarſus; it well deſerves its name both from its figure and ſituation. The baſe of the wedge forms the upper ſurface which is quadrilateral, with the ſhort diameter tranſverſe, and rough for ligaments. The edge of the wedge below is ſharp, and ſerves the ſame purpoſes; behind it is articulated by a concave ſurface, with the middle plane in the front of the os naviculare; before, by a convex one, with the ſecond metatarſal bone. Of the two four-cornered ſides the internal is nearly plane, with an articular facet near the upper edge, and another at the poſterior, joined to the laſt bone; the external has a concave articular facet for connection with the third cuneiform bone towards the upper and poſterior angle: they are both rough on the remainder of their ſurfaces for fibrous attachments.

The third cuneiform bone (externum, or medium, Alb.) is rather larger than the preceding, and longer from before backwards; it reſembles it much in figure and poſition. The baſe, which is above, and the edge below, give attachment to ligaments. Behind is a triangular articular ſurface, correſponding to one of the planes in front of the naviculare; before an oblong flat one in contact with the third metatarſal bone. The internal ſurface is marked by two articular facets, ſeparated by a rough depreſſion for ligaments, of which the anterior correſponds to the ſecond metatarſal bone, the poſterior to the ſecond cuneiform. The external ſide is rough anteriorly, and has a plane articular facet towards the upper and poſterior angle, in contact with a correſponding one on the inner ſide of the cuboides.

The laſt five bones of the tarſus are wholly cartilaginous at birth, and are gradually and ſolely developed from ſingle points of oſſification. They are not proportionably larger in this ſtate than when in their perfect oſſeous forms, in which reſpect they reſemble the carpus.

The articulation of the leg with the foot, the ankle joint.— To form this joint, the upper articular ſurface of the aſtragalus, nearly all the outer ſide, and the narrow cartilaginous facet on the inſide, are received into the cavity formed by the lower end of the tibia and fibula, and embraced cloſely by the two ankles. The correſponding ſurfaces are covered by cartilage, and united by ſeveral ligaments, the moſt efficient of which are placed at the ſides; the connection is much ſtrengthened by the numerous tendons which paſs over or near it to be attached to different bones of the foot.

The internal ligament (l. deltoides) is of conſiderable breadth; attached above to a part of the circumference of the internal malleolus, more eſpecially to its point, it deſcends a little obliquely backwards, and is fixed to the inner ſurface of the aſtragalus, and the neighbouring parts of the os calcis. It is compoſed of a conſiderable quantity of longitudinal fibres, of which the anterior and the moſt ſuperficial are the longeſt. On the inſide, the tendon of the tibialis poſticus paſſes over it, and is connected with it by its fibrous ſheath; it is contiguous alſo to the long flexor of the toes. On the outſide is a ſtraight rounded and thick ligament (l. medium perpendiculare) which deſcends from the lower extremity of the fibula a little obliquely backwards, paſſing under the tendon of the peroneus longus, and is attached to the outer ſide of the os calcis; it is formed of compact, longitudinal fibres. In front of this is another ligament (l. anterius malleoli externi), which paſſes from the anterior part of the point of the outer malleolus, forming a ſtrong flat band of fibres, frequently divided into two or more portions of conſiderable ſtrength, and is fixed to the aſtragalus in a depreſſion before the external articular ſurface. The front of the joint is ſtrengthened alſo by a collection of irregular fibrous bands, which deſcends from the anterior part of the lower extremity of the tibia, amidſt much cellular tiſſue and fat, and are inſerted partly into the aſtragalus cloſe to the termination of the articular pulley, and are partly continuous with the ligaments paſſing from this bone to the naviculare. Towards the back of the joint, we have ariſing from the fibula a ſtrong ligament (l. poſterius malleoli externi) paſſing nearly tranſverſely inwards, and fixed to the edge of the articular pulley at the back of the aſtragalus, cloſe to the outer margin of the groove for the tendon of the long flexor of the great toe. It is ſtronger than any of the preceding ligaments, and compoſed of numerous diſtinct packets of fibres. Immediately above this, and connected intimately with it, at its origin from the back of the external malleolus, is a tranſverſe band of fibres paſſing directly acroſs, or mounting a little obliquely, to be attached to the poſterior border of the articular ſurface of the tibia, and to the inner ankle. It increaſes a little the depth of the articular cavity behind, and might be regarded properly as one of the poſterior ligaments connecting the tibia and fibula. The ſynovial membrane is diſtributed as uſual, lining all the cartilaginous ſurfaces and the ligaments; lining alſo the narrow articular facets between the tibia and fibula, making this little joint communicate with that between theſe bones and the aſtragalus. It is looſe in front, where we find a conſiderable quantity of cellular tiſſue and fat; covered in this aſpect by the tendons of the tibialis anticus, the long extenſors of the great, and other toes, and the peroneus tertius; behind by the tendons of the tibialis poſticus, the flexors of the toes, and the peronei; partly in theſe ſituations, and on the ſides by the ligaments juſt deſcribed. In addition to the many tendons enumerated, this articulation is further ſtrengthened by the tendo Achillis behind, a powerful agent in preſerving its relations.

The motions which take place between the leg and foot are chiefly thoſe of flexion and extenſion; the lateral inflexions are extremely limited. In flexion, which is more confined than the oppoſite motion, on account of the diſpoſition of the articular pulley of the aſtragalus, this bone glides backwards on the lower end of the tibia, regulated by the two malleoli lying cloſe on either ſide; the poſterior ligament is ſtretched, the others undergo but little change; and luxation rarely occurs. In extenſion the motion may be continued, ſo as to make the foot form a very obtuſe angle with the leg; the external anterior ligament is diſtended conſiderably, the others leſs ſo, the poſterior is relaxed. In ſtanding on the toes this poſition is maintained by muſcular efforts, particularly by means of the tendo Achillis; the tibia reſts on the poſterior part of the pulley of the aſtragalus, and tranſmits the principal weight to the naviculare, inſtead of the os calcis, as in ordinary ſtation. The lateral inclinations of the foot on the leg, as far as this joint only is concerned, are extremely confined, owing to the lateral deſcent of the malleoli; in which reſpect they differ much from the lateral motions of the carpus on the fore-arm. The lateral ligaments are here reciprocally ſtretched or relaxed, as the foot is turned inwards or outwards. Diſlocations to either ſide occur more frequently than we might at firſt imagine from the apparent ſecurity afforded by the malleoli. Luxation outwards is the moſt frequent, the fibula breaking two or three inches above its lower end, ſo as to allow of the everſion of the foot; it is generally the conſequence of ſudden violence, as in jumping, or in falling on the foot from any height.

The articulations between the bones of the tarſus.—The aſtragalus is articulated by two, ſometimes three cartilaginous planes on its inferior ſurface, with correſponding ones on the upper ſurface of the os calcis. Theſe ſurfaces are preſerved in contact by a ſtrong collection of ligamentous fibres, paſſing directly upwards from the whole length of the oblique groove, between the articular facets on the upper ſurface of the os calcis to a ſimilar depreſſion on the under ſide of the aſtragalus, where it is attached to every point not occupied by articulating cartilage. The internal fibres lie deep between the bones, and are ſhort; the external ones are longer, and more in quantity, buried in the cellular tiſſue and fat which contribute to fill the vacancy obſerved in this part. Behind there are ſome parallel fibres paſſing down from the back of the aſtragalus to the os calcis, which concur in forming the ſheath for the tendon of the long flexor of the great toe; they are not numerous. This articulation is alſo ſtrengthened by the lateral ligaments of the ankle joint, eſpecially by the external, which paſſes immediately from the fibula to the os calcis. The ſynovial membranes offer nothing remarkable. The motions which have place here are always combined with others, and will be conſidered farther on.

The anterior convex articular ſurface of the aſtragalus is received into a cavity formed by the concave ſurface of the os naviculare, a ſmall ſpot of the os calcis, and completed below by ligaments paſſing between theſe two bones. We obſerve above a dorſal ligament, thin and flat, compoſed of fibres paſſing from the depreſſion called the neck of the aſtragalus to the upper rough ſurface of the naviculare; they ſometimes reach to the cuneiform bones. It is covered by the extenſors of the toes. Below is a very ſtrong ligament, paſſing from the anterior and internal parts of the os calcis obliquely forwards and inwards to be attached to the hollow in the lower ſurface of the naviculare. It is covered on the inſide by the tendon of the tibialis poſticus: above it is lined by ſynovial membrane, and forms the lower part of the cavity which lodges the head of the aſtragalus, to the ſupport of which it eminently contributes. It is very denſe in its ſtructure. There is alſo a ſhort and very firm band paſſing from the anterior part of the os calcis to the outſide of the naviculare, completing the cavity externally. This joint is lined by a ſynovial membrane, which communicates with the anterior articulation between the aſtragalus and os calcis, as before mentioned. It is ſpread over the correſponding ſurfaces and ligaments we have been deſcribing.

From what we have ſaid, it appears that the os calcis is firmly connected with the naviculare, though in contact only by a very narrow ſpot; the ligaments croſs the head of the aſtragalus in their courſe, and their apparent uſe is to ſupport the latter, at a point which appears ſo deficient, when examining the mechaniſm in the dry ſkeleton. The os calcis is more extenſively articulated with the cuboides by cartilaginous ſurfaces ſlightly concave and convex in oppoſite ſenſes. The joint is ſecured by two ligaments, a ſuperior or dorſal, an inferior or plantar. The firſt is broad and thin, compoſed of ſhort parallel fibres paſſing rather obliquely forwards from the upper and external parts of the os calcis, to the ſuperior rough ſurface of the cuboides. It is often formed into two ſeparate longitudinal bands. It lies under the peroneus tertius. The inferior ligament is the longeſt, and ſtrongeſt of all the ligaments of the tarſus. It is attached behind to the middle of the inferior ſurface of the calcis, paſſes horizontally forwards, and is fixed principally into the oblique protuberance obſerved on the lower ſurface of the cuboides. It is formed of a great number of fibres, divided into ſeveral bundles, which diverge rather as they approach the cuboides. The inferior ones, or the moſt ſuperficial, are much longer than thoſe more deeply ſeated, and are continued under the tendon of the peroneous longus, part of whoſe ſheath they form, to the poſterior extremities of the firſt and ſecond metatarſal bones. The upper plane is ſhorter in its courſe, and fixed behind the groove for the peroneus longus. The ligament is covered below by ſeveral muſcles of the foot, which have partly their origin from it. It ſhould be remembered that this joint is in the ſame tranſverſe line with the one between the aſtragalus and naviculare.

For the articulation between the naviculare and cuneiform bones we have in the firſt a cartilaginous ſurface divided into three planes, in the latter correſponding ſurfaces covered by articular cartilages continued laterally into their mutual articulations. It is ſecured by three dorſal ligaments, attached to the upper and lateral portions of the circumference of the naviculare, paſſing one internally to the firſt cuneiform, another in the middle to the ſecond, and a third more externally to the outer cuneiform bone. They leave intervals filled by cellular tiſſue: the internal is the largeſt; and thicker at its inferior edge. The plantar ligaments have been deſcribed as three alſo, but they are too irregular for diſtinction, appearing as fibrous bundles paſſing between the oppoſite bones, confounded at their attachment to the naviculare. This joint is ſtrengthened internally by an elongation of the tendon of the tibialis poſticus, which is attached to the baſe of the firſt cuneiform bone, and continuous with the more internal of the ligaments we have been deſcribing.

The articulation of the naviculare with the cuboides is formed by the contact of two ſmall plane cartilaginous ſurfaces, lined by their proper ſynovial membrane, and ſecured by numerous ſhort ligamentous fibres paſſing from bone to bone, occupying the remaining ſpace; they are very cloſe and compact. There is alſo a plantar ligament rounded in form, paſſing obliquely from the inferior and external part of the naviculare to the oppoſite point of the cuboides; and a dorſal tranſverſe band, croſſing from one to the other, covered by the extenſors.

The cuneiform bones are articulated with each other by cartilaginous facets connected by ligaments paſſing from bone to bone, deeply as well as ſuperficially. The dorſal ligaments are tranſverſe, and form really but a ſingle band, continued over the three, and attached in its courſe to each. The plantar ligaments are alſo tranſverſe, but not ſo marked; the one which goes from the firſt to the ſecond is the ſtrongeſt: they are covered by an extenſion of the tendon of the tibialis poſticus, one part of which is fixed to the ſecond cuneiform, another to the ſecond metatarſal bone; theſe are diſtinguiſhed from the ligaments by the oppoſite direction of their fibres. We find alſo many ſhort ligamentous fibres paſſing between theſe bones, as between many others of the tarſus, attached to the parts not occupied by cartilage: they add much to the ſtrength of union.

We have here a ſynovial membrane common to theſe joints, and that with the os naviculare above deſcribed. It is ſpread over the anterior ſurface of the latter, over the connecting ligaments, and dips between the cuneiform bones, lining their articulation throughout.

The articulation of the third cuneiform with the cuboides is by means of plane cartilaginous ſurfaces, provided with their diſtinct ſynovial capſule, and ſecured by ligaments. Of theſe the dorſal is oblique, ſmall and thin, uniting the oppoſite edges of bone; the plantar is conſiderably thicker, and more directly tranſverſe. Here alſo are many interoſſeous ligamentous fibres, fixed to the parts not covered by cartilage, or where the bones are not in immediate contact.

Motions of the tarſal bones on each other.—The motions which take place between the tarſal bones are very limited, if we except thoſe between the aſtragalus, and the os calcis and ſcaphoides. By this chiefly the foot is turned inwards and outwards; the lateral inflexions of the ankle joint aſſiſting the motion but little. In the movement which carries the point of the foot a little outwards, which depreſſes its internal and elevates its external edge, the naviculare glides on the head of the aſtragalus, and the os calcis on its lower articulating ſurfaces: the latter bones approach each other more cloſely, the interoſſeous ligament, and the external lateral one of the ankle joint are relaxed, the internal lateral ligament is ſtretched, eſpecially thoſe fibres which paſs to the calcaneum. In the oppoſite motion of twiſting the foot inwards, and bringing the ſole to face the other, the bones move in the contrary direction, the inner border of the foot is raiſed, and the external becomes inferior; the interoſſeous, and external lateral ligaments are diſtended. Theſe motions, which are very ſenſible, may be accidentally forced beyond their natural limits, and give riſe to injuries which are too generally referred to the joint of the ankle. The naviculare and cuboides may be moved up and down on the aſtragalus and os calcis, and the cuneiform bones have gliding motions on the naviculare, the cuboides, and between themſelves, by which the concavity of the foot may be a little increaſed or diminiſhed. The utility of theſe numerous articulations in enabling the foot to reſiſt the ſhocks it muſt often neceſſarily ſuffer, and in giving grace and eaſe to the motions of the lower extremity in progreſſion needs ſcarcely be inſiſted on: their great relative ſize and the very powerful ligaments ſubſervient to them make diſplacement of more rare occurrence than we might at firſt imagine, on conſidering the efforts they have to ſuſtain.

The metatarſus (mittelfuſs, Germ.)—is compoſed of five long bones placed horizontally and nearly parallel to each other, ſo as to form a gently convex ſurface above, and a concavity below. It is ſituated between the tarſus and the toes, and is analogous in many points to the metacarpus. The individual bones are diſtinguiſhed numerically, beginning from the inſide. The firſt metatarſal bone, that of the great toe, is by much the largeſt in volume, though rather ſhorter than the reſt; the ſecond is of the greateſt length; the third comes next to it, the two laſt differ but little: the four latter differ very little in ſize. They all contract a little in the middle, and ſwell at each end, particularly towards the tarſus, and are divided into two extremities and a body.

The tarſal, or poſterior extremity of the firſt, is oblong vertically, with a ſemi-circular articular cavity behind, reſting on the firſt cuneiform bone. The inner edge of the circumference, which is convex, gives attachment about its middle to a part of the tendon of the tibialis anticus; below is a blunt projecting proceſs, to which the tendon of the peroneus longus is fixed; and on the outer concave edge a ſmall ſmooth ſpot, which is in contact with the ſecond metatarſal bone.

The tarſal are much larger than the digital extremities of the other four, angular, and in cloſe oppoſition with each other. That of the ſecond is placed farther back than the firſt, is triangular, with the baſe upwards; it is wedged between the cuneiform bones, reſting on the ſecond by a concave triangular articular ſurface behind; on the firſt by a ſmall ſpot on the inſide, and on the third by one on its outer ſide. In the laſt aſpect there are two other articular facets in front of the laſt joined to the third metatarſal bone, ſurrounded by aſperities for ligaments: the edge above, and the point below are alſo rough, for the ſame purpoſes. The tarſal end of the third is triangular in the ſame direction as the preceding, articulated by a plane ſurface behind, with the third cuneiform bone. On the inſide are two ſmall facets contiguous to correſponding ones in the ſecond metatarſal; on the outſide a ſmooth ſpot above, articulated with the following bone, and a rough depreſſion beneath for ligaments. It is rough alſo above and below. In the fourth, the tarſal extremity is more quadrilateral: behind it is articulated with the front of the cuboides; on the inſide with the ſame bone, and with the third; on the outſide with the laſt metatarſal. Below, and in front of theſe articular ſpots, the bone is rough for ligamentous attachments. The tarſal end of the fifth or laſt metacarpal bone is larger than thoſe of the preceding. It preſents behind an oblique triangular articular ſurface for the cuboides; above and below rough and unequal borders, the former giving attachment to the peroneus tertius, and both to ligaments; on the inſide a ſmall articular facet in contact with the fourth; and on the outſide a rough eminence projecting backwards, to which the peroneus brevis is fixed, and a portion of the abductor of the little toe.

The bodies of the metatarſal bones are concave from before backwards below, and gibbous above, very irregular in form, and ſcarcely admitting of regular diviſions into ſurfaces. That of the firſt is of a triangular priſmatic form, with the upper ſurface convex, and inclined a little inwards; the inferior concave, covered by the flexor brevis of the great toe; the external flat and large, correſponding to the muſcles which lie between theſe bones. The bodies of the reſt may be regarded in four aſpects; the dorſal preſents in each a blunt riſing line, which divides the attachment of the interoſſei; the plantar offers a ſmooth ſurface for muſcular attachments; the internal and external exhibit variouſly inclined ſurfaces, of different breadths, continuous with the two former, ſmooth, and covered by the muſcles which ariſe from them, and fill the interſpaces. In the fifth the body is curved a little from within outwards, and its external ſide, or rather edge, gives origin in part to the abductor of the little toe ; the dorſal ſurface is inclined conſiderably outwards, and terminates on the inſide by a prominent line ; the plantar ſurface is covered partly by the flexor brevis of the ſame toe. In all the dorſal ſurface is covered by the tendons of the long and ſhort extenſors, by veſſels and nerves, and the plantar by the deep-ſeated muſcles and tendons in the ſole of the foot, by ligaments, and by larger blood veſſels and nerves.

The digital, or anterior extremity, is very ſimilar in all. It preſents a rounded articular ſurface, called the head, ſupporting the firſt phalanx of the toes : this extends further from above below than tranſverſely, in which direction it is compreſſed. The circumference is rough, offering above a ſenſible groove for ligaments, and on each ſide a hollow, in which the lateral ligaments are fixed. The articular ſurface is prolonged further below than on the dorſal aſpect, and terminates on each ſide by projecting tubercles. In the firſt this lower ſurface is divided by a prominent line into two pulleys, on which the ſeſamoid bones glide, which are placed below this joint of the great toe. In this bone alſo the articular ſurface has a much greater proportional breadth.

The metatarſal bones reſemble in ſtructure and formation the other long bones, with this exception only, that the ſmaller ones are ſometimes developed from two points of oſſification, one for the tarſal extremity, and body, another for the digital : in the firſt there are always three.

The articulations of the metatarſus with the tarſus.—The firſt bone of the metatarſus is articulated with the anterior ſurface of the firſt cuneiform ; the ſecond with the three cuneiform bones ; the third with the correſponding cuneiform ; the fourth and fifth with the cuboides. The oppoſite articular ſurfaces are covered by thin cartilage, and their relations preſerved by ligaments above and below ; they are all lined by ſynovial membranes common in general to theſe joints, and to the articulations of the metatarſal bones between themſelves.

The dorſal ligaments paſs from each metatarſal bone to thoſe bones of the tarſus with which they are articulated. From the firſt there paſſes a broad and thin band to the firſt cuneiform, attached to the ſuperior ſurface of each. From the ſecond, which is let in between the three cuneiform bones, we find three ligaments croſſing, one internally to the firſt, another in the middle to the ſecond, a third externally to the third cuneiform : the firſt and laſt are oblique in their courſe, the ſecond paſſes directly from before backwards. The dorſal ligament of the third is ſhort, and goes ſtraight to the third cuneiform ; thoſe of the third and fourth are attached to the upper ſurface of the cuboides ; they are more or leſs oblique, and by no means conſtant in their forms or ſituation, the dorſal ligament of the fourth being often attached to the third cuneiform. They are all covered by the extenſor tendons.

Of the plantar ligaments, which are analogous in direction and attachment to the dorſal, that paſſing from the firſt metatarſal is very ſtrong, and the joint is ſtrengthened alſo by an extenſion of the tendon of the tibialis anticus, which is fixed to the inſide of the tarſal end of that bone. The plantar ligaments of the ſecond are ſimilar to thoſe above. That which paſſes from the firſt cuneiform is thicker, and larger than the other, reaching to the baſe of the third metatarſal ; the other two are covered and ſtrengthened by a portion from the tendon of the tibialis poſticus. The inferior ligaments of the others are ſmall, yet diſtinct, and of various lengths. The plantar ligaments are much ſtrengthened by the numerous tendinous ſheaths which are found in the ſole of the foot, and particularly by that of the peroneus longus, which croſſes moſt of them as it paſſes along to reach the firſt metatarſal bone. The ligaments, both above and below, are compoſed of ſhort and cloſe parallel fibres, following longitudinal, oblique, or tranſverſe directions, according to the relations between the points to which they are fixed. They are ſeparated by intervals filled with cellular tiſſue, and giving paſſage to veſſels. The ſynovial membrane, lining the joint between the firſt metatarſal and cuneiform bones, is diſtinct, and offers nothing remarkable in its diſtribution. That lining the triple articulation, formed by the ſecond with the three cuneiform bones, is continuous with the ſynovial membrane, lining the articulation between the two firſt of theſe bones. A ſeparate one is found ſpread over the joint of the third metatarſal and cuneiform, and ſending off two ſmall lateral elongations, which dip between the articulations of the third with the ſecond, and fourth metatarſals. It often communicates with the former at the point where they are in contact. Another ſynovial membrane belongs to the articulation of the two laſt metatarſals with the cuboides, common alſo to that between the two former of theſe bones.

The articulations between the metatarſal bones,—are formed behind by the contact of lateral articular facets, with the exception only of the firſt, which touches the ſecond without being articulated with it. Theſe two bones are united by ſhort ligamentous fibres paſſing from one to the other, of conſiderable ſtrength ; the others are connected by dorſal, plantar, and interoſſeous ligaments. The dorſal are tranſverſe, and three in number, paſſing from one bone to the next, irregular in form, and attachment, appearing in ſome ſubjects as a ſingle tranſverſe band. The plantar are ſimilar in number and direction, but in addition we find ſeveral ſmall ſlips paſſing from the fifth to the three next metatarſals, ſeparated by cellular tiſſue. The interoſſeous ligaments between the poſterior ends of theſe bones are formed by numerous ſhort fibres, occupying the parts not covered by cartilage, and tending very materially to ſecure their relations. The anterior extremities of the metatarſal bones are not in abſolute contact, but they are firmly connected together by a tranſverſe ligament paſſing below them, and attached to each bone, reſembling the ligament deſcribed as paſſing between the digital ends of the metacarpal bones in its form and direction.

The metatarſal bones have but an obſcure motion on the tarſus, on which they may be ſlightly elevated and depreſſed. They may be moved alſo ſo as to approach each other in front, and augment the depth of the concavity of the ſole ; this effect is produced chiefly by the motion of the firſt and laſt towards the long axis of the foot, and is in conſequence of muſcular action : when the foot is flattened by preſſure they are forced farther apart mechanically.

The toes, forming the laſt diviſion of the foot, are five in number, placed horizontally ſide by ſide, compoſed of rows of ſmall bones extending longitudinally one beyond another. We reckon them numerically, beginning from within. The firſt and laſt are known alſo by the names of the great and little toe. The ſecond is rather longer than the firſt, the other three diminiſh ſucceſſively in length. We find three bones, named phalanges, in all, excepting the firſt, which has only two ; theſe are termed, from their ſituation, the firſt or metatarſal phalanx, the ſecond or middle, and the third or unguinal ; in the great toe the bone of the middle phalanx is deficient. The two bones of this laſt are very ſtrong, and exceed very much in volume the different rows of the other toes which are ſlender in form, and comparatively weak. The bones of the firſt phalanx are the longeſt ; thoſe of the ſecond are very ſhort, as alſo the third. They all ſwell conſiderably at the extremities, and are contracted in the middle part or body. They reſemble the fingers very nearly in the material points of their formation, differing from them chiefly in ſize and mobility.

The firſt phalanges are by much the longeſt, and the bones are more rounded than the correſponding ones in the fingers. They are hollowed below, particularly near the extremities, where the flexor tendons lie, the edges giving attachment to the ſheaths which confine them. The poſterior extremities are concave for the heads of the metatarſal bones, the anterior have condyles, and a middle depreſſion for the ſecond phalanx. The two oppoſite articulating ſurfaces between theſe bones and the correſponding ones of the metatarſus, are cruſted by cartilage, and ſecured by lateral ligaments, as in the fingers. Theſe are thick and ſtrong, paſſing from the end of one bone to the oppoſite. The joint is ſtrengthened below by a tranſverſe ligament, covering it from ſide to ſide, contributing to the ſheath of the flexor tendons; and is further ſupported by theſe laſt, by the extenſors, and the ſmaller muſcles which ſurround them. The ſynovial membrane is looſe and extenſive; in the joint of the great toe it lines the two ſeſamoid bones. Theſe ſmall bones are unequal in ſize; the internal is the largeſt, oblong, gibbous below, concave longitudinally above, and a little convex tranſverſely, covered in the laſt aſpect by cartilage, and reſting on the head of the metacarpal bone in the two hollows already mentioned, ſo as to be ſeparated by a ſmall interſpace. They are connected by ligaments to the firſt bone of the great toe, as the patella is to the tibia, and glide backwards and forwards in the different motions of the joint, defending it effectually below, giving an advantageous purchaſe to the muſcles which are fixed to them, and preſerving from preſſure the tendon of the long flexor, which runs between them. Theſe bones are rarely met with in the other articulations. The motions between theſe bones and the metatarſus may be effected in every direction, except rotation, and are in general more limited than in the fingers. The toes, however, can be inflected backwards, or extended on the metatarſus to a greater degree than they can be bent. The advantages of this mechaniſm, ſo widely different from what we noticed in the hand, may be particularly noticed in ſtanding on the toes, and in progreſſion, and will be examined hereafter.

The ſecond phalanges of the four leſſer toes are ſo ſhort and compreſſed longitudinally, as to have ſcarcely the uſual characters of the long bones. This is a diſtinguiſhing point, in comparing them with the ſecond phalanges of the fingers, which they otherwiſe reſemble in miniature, giving attachments in a ſimilar manner to flexor and extenſor tendons, and to the fibrous ſheaths of the former. The articulations are alſo analogous; the motions, which are thoſe only of flexion and extenſion, are more limited.

The laſt, or unguinal phalanges, five in number, reſemble thoſe of the fingers both in ſtructure and formation. That of the great toe is ſtrong and broad; the others are more than proportionably ſmall. This laſt difference is the principal one between them and the fingers; the articulations and motions are very nearly the ſame; the latter may be a little more limited. In children they are very moveable: this mobility diminiſhes as we grow up, and is often completely deſtroyed in advanced age, owing moſt probably to the confinement of our ſhoes. The metatarſal rows have three points of oſſification, the others have two, and very frequently only one.

From the aſſemblage of the bones we have been deſcribing, there reſults a long, broad, and partly vaulted baſis, for the ſupport of the weight above, ſecured by numerous and ſtrong ligaments binding the arch beneath. The principal points of bearing are on the lower part of the heel bone; the outſide of the foot in nearly its whole length, eſpecially the poſterior end of the metatarſal bone of the little toe; the anterior ends of all the metatarſal bones, and moſt conſpicuouſly that of the great toe, which is proportionably ſtrong. When the heel is elevated from the ground, the whole preſſure is on theſe laſt mentioned points, and on the toes, which compenſate, by their augmented breadth, their comparative want of ſolidity. The vaulted form gives a ſpace in which the veſſels and nerves can paſs free from compreſſion; and the number of the articulations, by diſtributing the ſhock over numerous ſlightly yielding ſurfaces, prevents the injurious effects which might otherwiſe ariſe from leaps, or falls on the feet.

Mechaniſm of the lower extremities.—In ſupporting the trunk, the hip bones are placed between two oppoſite efforts; *viz.* the weight of the body tranſmitted by the ſacrum; and the reſiſtance oppoſed by the limb below in the direction of the cotyloid cavity. The depreſſing impulſe acts in a plane poſterior to that of ſupport, tending to make the hip bones move backwards on the thighs, if they were not counterbalanced by muſcular efforts. The baſe of ſupport, as far as regards the oſſa innominata, is contained between the plane of the vertebral column behind, and that of the thigh bones in front; a ſpace which varies in different individuals, and which is comparatively narrow in infancy, from the more oblique direction of the hip-bones, which brings the thighs more immediately under the vertebral column. As the oſſa innominata become more horizontal, the baſe of ſupport is rendered wider, and the muſcles being at the ſame time more fully developed, give it additional ſecurity. This is one ſource of the difference in gait in manhood and infancy. Another is found in the diſpoſition of the cotyloid cavities. As they are at a diſtance from the points of oſſification, they are almoſt wholly cartilaginous for ſome time after birth, and therefore can offer but a feeble reſiſtance to the thighs, quite inſufficient for ſtanding or progreſſion, until the place of cartilage is ſupplied by bone. Add to this, that the two joints are comparatively nearer to each other; which circumſtance, though it give facility, muſt neceſſarily diminiſh firmneſs. The greater proportional diſtance in the adult throws the thighs further apart above. In females this diſtance is greater than in the male, which gives a peculiarity to their walk, a more obſervable rolling of the hip in the ſucceſſive advancement of each limb. This is not to be ſeen in the infant female, where the poſition and form of the hip bones differ but very little from thoſe of the male of the ſame age.

The femur, which is the only bone in the thigh, is curved conſiderably forwards in the middle; hence a larger ſpace is left behind for muſcles; and the baſe of ſupport, afforded by this bone to the trunk, is directed forwards, ſo that the latter is ſuſtained in the direction, in which it has the greateſt tendency to fall. The neck of the bone, beſides increaſing the extent of rotation, enlarges tranſverſely the baſe of ſupport; gives the body a greater firmneſs in ſtanding, without impeding progreſſion, ſince the head of the bone, and not the body, is the centre of motion. If the thigh bones poſſeſſed no neck, but were kept equally far apart, by increaſing the diſtance between the cotyloid cavities, the attitude of ſtanding would be equally ſecure, the tranſverſe baſe of ſupport being ſtill the ſame; but progreſſion would be impeded, as it actually is in the female, from the greater tranſverſe diameter of the pelvis. The head of the femur, ſunk into a deep cavity, is forced, in ſupporting the trunk, againſt the moſt reſiſting part of this cavity, *viz.* under the anterior ſpines. The ſtrong ligamentous bands which ſtrengthen the capſule in front and above, are ſo diſpoſed as to augment the reſiſtance to any effort of the thigh-bone in that direction, and to reſtrain any part of the head which may not be contained in the acetabulum. The interior ligament alſo adds to the firmneſs of the joint; preventing, by its tenſion, the diſplacement of the articular ſurfaces in every effort which forces the head upwards; an effort which, from the preſſure of the trunk, is almoſt conſtantly operating. In the infant, the body of the bone is nearly ſtraight, a conformation unfavourable to ſtanding, according to the reaſons above alledged: the neck is ſhorter, and conſequently the baſe of ſupport diminiſhed; it is cartilaginous, and therefore leſs able to endure, for any time, an attitude which demands ſolidity in the ſuſtaining parts. Theſe are other reaſons for the inſecurity of the ſtation and progreſſion of young children, and ſhew by contraſt the advantages of the form of the adult bone.

In the knee, we are ſtruck with the extent of the articular ſurfaces, and the number and ſtrength of the ligaments which connect them, ſo well adapted to ſuſtain the weight tranſmitted by the thighs; the crucial ligaments limiting and maintaining the extenſion of the leg, preventing it from paſſing in this direction beyond the axis of the thigh; the patella in ſome meaſure reſtraining its flexion, protecting the joint, and more particularly favouring the action of the extenſor muſcles, which play ſo important a part in the functions of the lower extremity. The perpendicular direction of the leg is very advantageous in giving firmneſs; to this end alſo the immobility of the two bones which compoſe it ſeems directed. The tibia, ſolid and broad at either end, alone receives the preſſure and continues it to the foot; the fibula ſerves principally to afford attachments to muſcles. This diſpoſition, ſo different from that obſerved in the analogous part of the upper extremity, bears an obvious relation to its different function. In infancy the patella is ſcarcely perceptible; its abſence muſt be unfavourable to the power of the extenſors, and may be one cauſe of the feebleneſs obſervable at that period; and further, its want is felt in kneeling.

The foot is admirably adapted to its office of ſuſtaining every effort continued from above. It is articulated at right angles with the leg, through which it receives the weight of the body in a perpendicular direction, bearing directly on the upper ſurface of the aſtragalus, the whole length of the foot reſting on the ground. The articulation is ſituated nearer to the poſterior than to the anterior part of the feet, which gives to the baſe of ſupport a greater extent forwards, a direction towards which the line of gravity naturally inclines. The lateral deſcent of the malleoli materially ſecures the firmneſs of the ankle joint. The breadth of the foot, increaſing gradually towards the front, the length of the metatarſal bones, the direction of that which ſuſtains the great toe, its ſituation and want of mobility, are other circumſtances marking the diſtinction between the hand and foot, and adapted to increaſe the ſolidity and extent of baſe afforded by the latter. The functions of the foot are aſſiſted alſo by its concave form, which enables it to gain a kind of hold of the bodies on which it reſts, and to accommodate itſelf to unequal ſurfaces, an advantage almoſt deſtroyed by the uſe of ſhoes, but eminently conſpicuous in thoſe people whoſe feet are not cramped by artificial means of defence. In its poſterior half nearly it reſts on the ground by its outer ſide, compoſed of the ſolid bone of the heel, and the os cuboides, the inner ſide repreſenting an arch, and placed at a diſtance from the plane below; in the anterior half the weight is principally ſupported by the inner ſide, where we find the ſolid bones of the great toe very little aſſiſted by the external edge.

Every thing in the ſtructure of man evinces that he is deſigned by nature for the erect poſture: we ſhall notice here thoſe proofs only which are deducible from the framing of the extremities. One of the moſt obvious is the great diſproportion in the reſpective lengths of the upper and lower limbs, and the greater comparative ſtrength of the lower. Other marks are found in the width and direction of the hip bones, in that of the neck of the femur, in the articulation of the leg at right angles with the foot, in the ſize and length of the latter, and the predominance of its ſolid over its moveable parts. We may remark alſo the flattened cheſt, and the ſhoulders ſet off by long clavicles, ſo very different from the conſtruction of theſe parts in quadrupeds, where the cheſt is compreſſed laterally, and the anterior extremities approach each other in front for the better ſupport of the body. The form of the hand, and the modes of articulation between the ſeveral bones of the upper extremity, are among the numerous and evident arguments that the erect poſture is natural to man, and we believe we may add, peculiar to him. In all the poſitions, produced by different motions, this poſture is more or leſs preſerved; ſo that, before we enter on progreſſive movements, it will be well to conſider ſeparately the ſimple act of ſupporting the body, which they neceſſarily include.

Station—or the act of ſtanding, in man, as far as the lower extremities are concerned, will be the firſt point for our obſervation. In this attitude it is neceſſary that the perpendicular line, which paſſes through the centre of gravity of the whole body, ſhould fall ſomewhere in the ſpace intercepted between the two feet, or on the ſole of the foot itſelf, if we are ſupporting ourſelves on one only. This centre of gravity, when the body is erect, has been proved by Borelli to be placed between the hip bones, "inter nates et pubem," in the human ſubject. To favour this diſpoſition, we find a vertebral column curved alternately in oppoſite directions, and placed obliquely with regard to the direction of the oſſa innominata, by which means the diſtribution of the ſoft parts is more eaſily managed, the balance preſerved, and permanent ſtation much facilitated. If this obliquity did not exiſt, and the vertebral column had been ſtraight, it would approach too nearly the line of direction of the leg and thigh, a diſproportionate quantity of the maſs of the body would be placed in front of the line paſſing through the centre of gravity, which would continually tend to make the body fall forwards in prolonged ſtation or progreſſion. In the orang-outang the angle, which the vertebral column raiſed perpendicularly makes with the hip bones, is much more obtuſe than in man, and the equilibrium is preſerved by the length of the arms; the ſame may be obſerved of the gibbon, the ſimia lar of Linnæus. In quadrupeds this angle, under ſimilar circumſtances, is ſtill more obtuſe, and the efforts they make to remain upright on the hinder feet are continued with difficulty, more eſpecially if not aſſiſted by ſome other peculiar advantages of conſtruction, as in the bear, for inſtance, by the length of the heel. In man, the hip bones united to the ſacrum form a circular ſupport, by means of which the columns below are not inclined to the trunk, but ſuſtain it in perpendicular lines. If they had converged above, they would have formed an angular ſupport, not ſo capable of reſiſting the preſſure, and requiring a conſtant and powerful exertion on the part of the adductor muſcles. As it is, the columns are preſſed on perpendicularly by the tranſverſe width of the hip bones, ſo that the preſſure may be ſaid to render them more firm and ſteady. The long bones of the lower extremity in man are placed nearly vertically on each other, and on the foot. And we may juſt remark, that even in ſtation a ſucceſſion of columns of the ſame ſize is probably more advantageous than a ſingle one, equal in bulk and length to the whole: this has been demonſtrated in the caſe where the weight is upheld by columns ſuppoſed to be flexible. The direction of the head and neck of the femur has been already mentioned as increaſing the baſe of ſupport, and we may add that the oblique poſition of the latter decompoſes, in ſome meaſure, the preſſure of the trunk from above, and renders it leſs ſenſible than if it had been vertical; avoiding at the ſame time the diſadvantages ariſing from an inclined poſition of the whole columns, as mentioned above. By the arch of the necks alſo the thigh bones are projected from under the hips, and ſuſtain the trunk with greater conſtancy and freedom than if they had been placed vertically beneath it during its different inclinations. The thighs, charged with the whole weight above, tranſmit it to the leg at the knee joint; ſomewhat differently, however, in the adult, and in the aged. In the latter the ſpine is bent forwards, and to preſerve the balance the thighs are neceſſarily alſo bent, and preſs obliquely on the leg, a diſadvantageous bearing, as requiring greater muſcular efforts, and ſoon becoming on this account wearisome. It is through the tibia alone that the preſſure is communicated to the foot, which finally ſupports the whole weight. The arch of the latter is favourable to ſtation only inaſmuch as it favours the adaptation of the ſole to inequalities of ſurface. In progreſſion it may give eaſe and grace, but the long and ſomewhat flattened foot is probably beſt ſuited to firmneſs of ſtation. The concavity is leſſened by the preſſure, which acts moſt ſenſibly on the anterior and more moveable part: it is very evident, when the foot comes with force to the ground, and it may be proved alſo by the aching and uneaſineſs produced by wearing ſhort ſhoes, which impede the elongation of the foot. A queſtion has ariſen concerning the moſt advantageous baſe of ſupport, or what opening between the two feet is beſt ſuited to ſecurity of ſtation. An anſwer equally applicable to every caſe cannot readily be found; the nearer it approaches a ſquare, including the feet, the better. Still different individuals muſt require different baſes as ſuited to their own form. In every caſe, if the ſeparation be too wide, the limbs loſe their perpendicular bearing, and become inclined to the trunk. The ſmaller the angle made by two lines produced backwards in the direction of the feet, the better: it ſeems, indeed, that a parallel direction of the two feet is the moſt natural, as we ſee it in children and in the greateſt number of adults, eſpecially of thoſe who have not been inſtructed by art. The body has a tendency to fall forwards, which is partly counteracted by the length of the foot; increaſing the baſe of ſupport in the anterior direction. Now if the foot be turned much outwards, the baſe is neceſſarily ſhortened towards the front; and, as in ſtation, the trunk has no diſpoſition to fall laterally, what the baſe gains in that direction is in no degree equivalent to what is taken away from the other. The ſame obſervation applies to turning the toes inwards; but as this never takes place to any conſiderable degree, an abuſe of it is leſs to be apprehended. The unnatural poſition, in which education teaches us to place our feet, with the heels forming an obtuſe angle behind, is contrary to the whole mechaniſm of the limbs, is uneaſy, and inſecure. In different gymnaſtic exerciſes the feet are placed ſo as to offer the greateſt poſſible reſiſtance to the probable direction of the effort they will have to withſtand. In wreſtling, where the force in the firſt inſtance is generally applied laterally, we obſerve the feet parallel, and at a conſiderable diſtance from each other. Conſtant attention, however, is abſolutely neceſſary to change this baſe, if any unexpected impulſe be made in a contrary line. A deficiency in this reſpect is the reaſon why inexperienced wreſtlers are ſo readily pulled down forwards, or thrown on their backs, their exertions being uniformly directed to oppoſe the expected ones of their adverſaries; if theſe be ſuddenly altered, there is no adequate power of reſiſtance. In boxing, the baſe is increaſed from before backwards, the feet are placed nearly at right angles and far apart, the knees are bent a little, and the trunk lowered. Here the impulſe is expected in front, and the attention is particularly directed to oppoſe it in that point. This, in ſhort, is one of the great principles obſerved not only in theſe exerciſes, but in every laborious exertion, as in puſhing or pulling, where the line of oppoſition does not vary. Whatever be the direction or diſtance of the feet from each other, no muſcular effort can prevent the fall of the body, whenever the perpendicular line from the centre of gravity falls without the quadrilateral ſpace intercepted between the feet. And a man can ſupport a weight much heavier than himſelf, provided that the line from the centre of gravity of ſuch body fall within the baſe of ſupport.

Our obſervations hitherto are principally applicable to ſtation, with the trunk erect. Let us now ſuppoſe the feet fixed ſecurely on the ground, and the trunk moving in different directions by means of the articulations of the hip with the thigh-bones. In bending forwards, if the motion be prolonged conſiderably, the centre of gravity is no longer ſupported, and a fall is the immediate and neceſſary conſequence. We have before remarked, that the articulation of the ſacrum with the oſſa innominata is in a plane poſterior to that of the feet. Now, if in bending forwards, the hip-bones move on the thighs, ſo as to bring the two baſes into the ſame plane, the centre of gravity is eaſily thrown forwards beyond them, and a fall is the reſult. To counteract this, when the trunk is bent much forwards, we at the ſame time carry the upper part of the lower extremities backwards, the feet remain advanced, the leg and thigh are inclined backwards, ſo as to form an angle with the body. In extending the body on the thighs, and carrying it back beyond the perpendicular, as there is no extended baſe of ſupport behind, analogous to that formed by the feet in front, we are obliged to bend the knees, in order to bring the centre of gravity within the ſpace occupied by the feet. If the lower extremities are maintained in an upright poſition, while the trunk paſſes behind the perpendicular line, a fall is inevitable. Lateral inclinations of the trunk on the thighs are neceſſarily confined; ſince, in order to lower it on one ſide, the oppoſite limb muſt be proportionably raiſed; when both feet touch the ground, it is almoſt completely prevented, ſo that the lateral balance is ſeldom loſt, eſpecially as we can at pleaſure widen the baſe of ſupport.

The power of ſtanding on the toes reſults from the mode of their articulation with the metatarſus, which allows of extenſion or inflection upwards, beyond the axis of the latter. By this mechaniſm we reſt on the whole length of the toes, not merely on their points, which would be utterly incapable of ſupporting the weight; here too the ſeſamoid bones are eſſentially uſeful, the preſſure bearing directly on them, as it does on the patella in kneeling. In this attitude the feet are extended on the leg, and form an obtuſe angle with the toes, which conſtitute the baſis of ſupport; the legs and thighs are in the ſame ſtraight line, and the trunk is projected a little forwards by the elevation, ſo that the centre of gravity is brought over the contracted plane, which now forms the baſe of ſupport, leſſened very much in length poſteriorly by the loſs of the tarſus and metatarſus. The ſame difficulties occur if we ſtand on any pointed, or narrow body, and for the ſame reaſon, *viz.* the diminution of the ſpace in which the vertical line from the centre of gravity muſt fall, in order to preſerve the equilibrium. This applies alſo, and more forcibly, to the caſes in which we ſtand on the toes, or heel of one foot only. In the laſt inſtance the foot is bent, the ſole elevated, the rounded heel alone touches the ground by a very limited ſurface, great muſcular exertion is required to keep the line of gravity vertical, the body vibrates on every ſide, and the attitude is neceſſarily ſoon loſt or diſcontinued. We have not ſo much difficulty in ſtanding on the heels of both feet, though this is far leſs eaſy than on the toes, on account of the points on which the weight reſts. Standing on a ſingle foot, with the whole ſole on the ground, is an attitude more eaſily maintained, on account of the greater length of contact, and the leſs muſcular exertion neceſſary to inflect or erect the trunk ſo as to bring the line of gravity within it. In this poſition the body is more or leſs inclined on the limb which ſupports it, and may be moved with facility in every direction by means of the joint at the hip. The long neck of the thigh-bone is here eminently uſeful, by widening the baſe of ſupport afforded above to the trunk; and the poſition cannot for an inſtant be maintained by animals, who, beſides other obſtacles, have a very ſhort neck to the femur. It is obvious that ſtation on one foot muſt be more difficult than on two, as in the laſt caſe it is not only the feet, but the plane intercepted by them, which form the baſe, and much leſs exertion is required to keep the line from the centre of gravity within it. We muſt have obſerved alſo, that when in ſtation on one foot, the trunk is much inclined in any direction, we throw out the other limb in the oppoſite one, in order to keep the centre of gravity vertical to the baſe: and if we ſtand on the toes or heel of one foot, not only the other leg, but the arms alſo, are called into action to preſerve the equilibrium, which is perpetually loſt and regained by the tottering trunk, and ſhuffling baſe. A fixed ſtability is utterly prevented by the difficulty of keeping the balance even under the greateſt muſcular exertions.

In ſitting, the ſupport is afforded by the tuberoſities of the iſchia, the thighs and the interval between them, and by the legs alſo, if we ſit on the ground with them extended. This is a firm poſition, eaſily continued, eſpecially if the body is inclined a little forwards over the baſe; if it is inflected backwards a fall may eaſily take place. On this account we have generally backs to our ſeats, to allow the trunk to recline, when the muſcles are fatigued by ſupporting it in its poſition of inclination forwards. The legs and thighs are concerned only in a ſecondary way in this poſture, as the principal ſupport is afforded by the tuberoſities of the iſchia reſting immediately on the ſurface below.

Kneeling is another attitude in which the lower extremities are employed, but the baſe of ſupport is extended poſteriorly, conſiſting of the ſpace included by the legs, which are projected backwards under the trunk. Hence the body, if erect, is diſpoſed to fall forwards; we require a reſting place in front, as we throw the hips backwards, to bring the line of gravity over the legs. This poſture is far from an eaſy one, ſince it requires a conſtant and unfavourable exertion of muſcular force. The uſe of the patella has been already explained.

The importance of the general law, by which it is neceſſary that a vertical line paſſing through the centre of gravity ſhould fall on ſome point within the baſe of ſupport, is ſtrikingly exemplified by the following obſervations. If we ſtand with our back and feet touching a wall, and then make a profound bow forwards, we inevitably fall, as the vertical line from the centre of gravity ſoon over-reaches the baſe of ſupport. Again, when ſitting with the trunk and legs perpendicular to an horizontal plane, we cannot riſe from our ſeat; becauſe the centre of gravity of the trunk falls far behind the feet: we are obliged conſequently either to incline the trunk very much forwards, or draw the feet backwards under it, in the firſt caſe changing the centre of gravity, in the latter the baſe of ſupport; and then by muſcular efforts the thighs are eaſily extended on the legs, the trunk ſuſpended, and the whole body erected; operations extremely difficult, if not impoſſible, ſuppoſing the original poſition had been preſerved. Our notions of ſtation would be very imperfect if we did not take muſcular exertions into the account; it is in vain that we place a dead body ſo as to bring the centre of gravity over the baſe of ſupport; the bony columns are no longer regulated by the varied efforts of numerous muſcles, as in the living ſubject; the machine is incomplete, and inſtantly gives way to the preſſure. The ſame phenomena occur if fainting comes on in the erect poſture; the head and neck incline forwards, as alſo the trunk; the bones bend on the thighs, the latter on the legs, and theſe again on the feet. We muſt not therefore confine our attention to the idea of bony columns preſſing vertically on each other, but recollect that they have highly moveable articulations, which require ſome ſtrong external efforts to give them poſitive ſtability. Theſe exertions are more or leſs powerful as the bones depart more or leſs from a vertical bearing on each other. Hence the anterior extremities of quadrupeds poſſeſs fewer and leſs powerful muſcles than the poſterior: as, in the firſt inſtance, the bones are directly extended on each other, and preſs vertically on the ground; in the laſt, they form angles more or leſs open, which can be preſerved only by a conſtant exertion of muſcular force. The elephant is an illuſtrative exception to this obſervation; his hind limbs are nearly vertical columns; a mechaniſm which diminiſhes the quantity of muſcle otherwiſe neceſſary to ſupport his enormous bulk. In inſects, on the other hand, the joints are bent at very acute angles; a ſtructure leſs inconvenient than we might at firſt ſuppoſe, as on account of the ſmalleſs of their body, the weight is diminiſhed in a ſub-duplicate ratio to their ſize. In birds who ſleep perched on trees there is a peculiar conſtruction, by which the mere ceſſation of muſcular action, the allowing the body to ſink, and the knees to bend, induces a mechanical contraction of the toes, which graſp firmly the body on which they reſt, and ſecure their poſition when at rooſt. In the grallæ tribe, in the ſtork for inſtance, who ſtands motionleſs for hours waiting for his prey, there is a particular conſtruction in the articulation of the knee, which enables him to ſtand without much muſcular exertion.

Progreſſion—may be effected in many different ways, of which we ſhall examine only the moſt ordinary and ſimple. In walking, the action, which carries the body forwards, backwards, or to either ſide, conſiſts in alternate motions of the lower extremities, in which each of them becomes, in its turn, the fixed point on which the whole weight of the body is ſupported; the limb which moves, giving in its elevation an impulſe to the trunk by means of the hip bone. Each of theſe motions is called a ſtep, and a ſuſtained ſucceſſion of them conſtitutes progreſſion: and in order to underſtand the latter, we ſhall examine the mechaniſm of the ſtep under different conditions. In walking, if we ſuppoſe both feet to be on the ſame tranſverſe line, the limb (ſay the left) which makes the firſt ſtep, is raiſed from the ground and advanced, by bending the hip joint; it is then extended, and laſtly, the foot preſerving its advanced poſition, is fixed on a different ſpot; ſo that the centre of gravity of the body which, during the advance of the left leg, was ſuſtained by the right, is moved forwards by a ſimultaneous movement of the trunk; and the line of gravity falls between the two feet. If the ſtep is ſhort, the hip and trunk move but little; if it be long, and the left leg carried far beyond the right, there is an evident rotation of the right hip, and conſequently of the trunk on the correſponding thigh. By this horizontal rotation, which carries the left ſide of the body obliquely onwards, the extent of the ſtep is greater than it would have been by the ſimple bending the thigh; and we ſee it in fact moſt evidently in long ſtrides, where the rotation is ſo great, as to bring the ſhoulder of the advanced ſide immediately in front, the hip moving through the quarter of a circle, giving thereby an additional impulſe to the limb below. As the ſtep is ſhorter, this lateral rotation is leſs obſervable, till in ſome caſes it can be no longer noticed. It is more evident in the female, from the greater tranſverſe diameter of the pelvis; and is particularly ſtriking in individuals who have a ſtiff, or anchyloſed hip joint, where the limb cannot be advanced by bending the thigh. The ſhort ſtep is effected, on the contrary, chiefly by the alternate flexions and extenſions of the joints of one extremity, uninfluenced by any movement of the trunk on the other.

If the feet are not in the ſame tranſverſe line at the commencement, the limb, which is behind, and inclined to the trunk, is the one to be moved forwards. Here the foot riſes, each part quitting the ground ſucceſſively, from the heel to the toes, by a kind of circular motion. The limb is thus elevated and advanced, and the centre of gravity is carried in the ſame direction, which latter is effected with greater facility, as the body at the ſame time leans a little forwards. When this impulſe is carried to its full extent, the toes are detached from the ground by the thigh being ſuddenly bent on the hip, which has been moved forwards, and the limb is carried on as in the former caſe, the other remaining fixed as the temporary ſupport. The hip and knee joints are then extended, and the foot bent on the leg. The foot touches the ground firſt by the heel: this is ſucceeded by a circular motion of the anterior part of the foot round this fixed point, and a correſponding motion of the leg in the ſame direction, which brings it to a vertical line at the time that the toes begin to bear on the plane below. In theſe circular motions the foot is ſenſibly elongated, and its concavity leſſened by the preſſure, its vaulted form, and the number and mode of its articulations imparting a degree of eaſe and grace to the whole motion which we look for in vain, where the foot is flat and ſtiff, and the whole ſole quits, or reaches the ground at the ſame inſtant. There is, in this caſe, an awkwardneſs of gait, and a real inability of walking with promptitude and vigour. This ſtep we have been deſcribing takes place ſucceſſively in each limb in progreſſion; and differs from the preceding in being more extenſive, and depending more importantly on the foot. The impulſe which its elevation communicates to the trunk will be influenced however materially by the knee: if this is bent in proportion as the foot riſes, the limb loſes in one action what it gains by another; the impulſe will be ſtronger as the knee is kept more extended. And when the foot is detached at once, without this rotation, no impulſe will be given to the hip by the limb in motion: if the pelvis roll on the thigh which is fixed, it muſt be by an independent muſcular action, as in the former caſe. In every caſe, as ſoon as the foot has left the ground, the trunk ſupports the limbs; and carries it forwards. The mechaniſm of the ſtep backwards will be eaſily underſtood from what has been ſaid: we obſerve only that the foot is raiſed more immediately by bending the knee; and that when the ſtep is prolonged, there is an evident horizontal rotation of the trunk in the ſame direction. The ſide ſtep is produced by gently bending the knee to detach the foot from the ground, and then abducting the thigh; or by lifting the whole limb by a lateral inclination of the trunk on the oppoſite one, and then ſeparating them, the knee being all the while extended.

Walking is a ſucceſſion of theſe motions, and requires for its regularity an equal length of both limbs; a ſhortneſs of either limb induces a ſinking and relative inclination of the whole trunk to the correſponding ſide, every time that the deficient extremity touches the ground. In the moſt natural mode of walking, one foot does not quit the ground entirely, until the other touches it wholly, or in a great part of its length: the latter begins to fix itſelf while the former ſtill reſts on its point; the vertical line from the centre of gravity, which fell on one foot during the tranſportation of the other, being carried forward, and dropping at this time between the two. When the advanced foot is firmly fixed, we throw on it the centre of gravity; the ſame motion neceſſarily projects the whole body forwards, and a ſucceſſion of ſimilar phenomena takes place. At each ſtep the impulſe given to the trunk by the limb which has juſt quitted the ground produces an undulatory motion up and down, and at the ſame time an horizontal rotation alternating from one ſide to the other. It is the latter which, from not being ſuſtained equally, produces the deviation from the ſtraight line in walking forwards, ſo conſtantly obſerved if we walk blind folded, where conſequently we cannot correct incidental errors by the ſight. The beſt chance of walking ſtraight in this caſe is by taking very ſhort ſteps, and for the reaſons inſiſted on above. In fact, the centre of gravity is not, when we carefully endeavour to attain it, moved forward in the ſame ſtraight line, but varies more or leſs between the lines deſcribed by the feet at every ſtep, in a degree proportionate to the extent of each. This is ſcarcely noticed, but is evident from this ſimple experiment. If we ſtand at any diſtance from a ſmall perpendicular rod, and fix our eyes on any point ſome way behind it, and in the ſame ſtraight line, we ſhall, as we advance to the rod, find this point alternately to the right and left of it, as we move each limb. A proof that the trunk is not carried as in a ſtraight line, but deſcribes a tortuous one, winding from one ſide to the other. Another conſequence of this rolling of the trunk on the oppoſite limbs in ſucceſſion, is a ſwinging motion communicated to the upper extremities: theſe move, moſt commonly, in an oppoſite way to the feet; that is, the right arm moves on at the ſame inſtant that the left leg propels the trunk. The uſe of this croſs motion of the arms is ſuppoſed to be that of correcting the lateral impulſe given to the trunk by the leg in its elevation. In every caſe of progreſſion there muſt be a regulated degree of flexions and extenſions, which is in ſome inſtances provided for by the mechaniſm of the bones, and their ligaments, but in all depends principally on an uniform ſucceſſion of ſuſtained muſcular actions. The greater difficulty and fatigue experienced in walking up an aſcending plane depends upon the greater degree of flexion neceſſary to raiſe the limb from the ground; this muſt be increaſed as the plane becomes more vertical; the heel is at the ſame time lower than the toes, and muſt paſs through more ſpace in each elevation than in the ordinary caſe of walking on plain ground. Walking down hill is for the ſame reaſons leſs difficult; there is leſs occaſion for extenſive muſcular action. The object is to regulate the impulſe which the trunk eaſily acquires, and to keep the centre of gravity over the feet, by throwing the trunk a little backwards, inſtead of leaning forwards, as in the preceding caſe. In aſcending alſo we have each time to elevate the weight of the body by muſcular powers; in deſcending we have only to prevent it from ſinking too faſt. Mounting ſteps, or a ladder, or deſcending either, are ſtill more difficult, as the reaſons above given apply more ſtrongly.

Running differs from walking chiefly in the rapidity and force with which the motions of the lower extremities are executed. The mechaniſm by which they are produced is nearly ſimilar; the remarkable differences are, that the toes only touch the ground, and the whole trunk is inclined very conſiderably forwards. In conſequence of the firſt circumſtance, a ſmall ſurface only is in contact with the ground; and this can be more rapidly applied and detached, while the extenſion of the foot upon the leg adds to the length of the limb. From this ſmall extent of the baſe of ſupport ariſe the frequent falls in running from trifling obſtacles, or ſlight lateral impulſes; and hence, in this mode of progreſſion, we ſhould conſtantly endeavour to preſerve the balance, by preventing the centre of gravity from being removed too quickly from the leg behind, or from being thrown too ſoon on the one in advance. Running is alſo inſecure from the ſhort time allowed for fixing the point of ſupport; and hence poſitive ſtability is leſſened inverſely as the neceſſity for it is increaſed by the quick tranſition of the centre of gravity from point to point. At each ſtep the trunk is ſuddenly and violently carried forwards by the limb which has juſt left the ground, and which muſt be immediately and conſiderably advanced to ſupport the centre of gravity. In running very faſt, eſpecially on a declivity, ſo powerful an impulſe is communicated to the trunk, that it is almoſt impoſſible to ſtop ſuddenly; we gradually ſlacken our pace, ſtill projecting the limbs to ſupport the trunk till the impulſe is weakened. In running up an acclivity we always bend forwards, to aſſiſt the propulſion of the centre of gravity, which is effected under many diſadvantages; we generally do ſo in running on plain ground, though, when we run carefully, the head and ſhoulders are thrown back to counterbalance the impulſe below. When from fear, or inability to continue the muſcular exertions neceſſary to maintain this poſture, the trunk is neither thrown back, nor even kept vertical to the horizon, the runner appears to yield entirely to the impulſe, to commit himſelf almoſt to chance; his only endeavours being to throw his legs out rapidly and to the greateſt extent, to ſuſtain the increaſing velocity with which the centre of gravity is carried onward: the ground covered at each ſtep is really immenſe, the power of balancing is totally loſt, and the ſlighteſt inequality of ſurface is ſufficient to overturn him with the rougheſt violence. If he is ſteady enough to reach the bottom in ſafety, he continues his courſe a very conſiderable way before the impulſe is deſtroyed, and the power of regulating his movements recovered. In running, the lateral rotation of the hip and trunk on the thigh is extenſive, from the length of the ſteps; and the ſame cauſe produces an equally great and rapid motion of the oppoſite arm to preſerve the equilibrium, which is more eaſily loſt than in walking.

In leaping, the body may be raiſed vertically, or with any degree of obliquity. The joints of the lower extremities are firſt cloſely bent, and then ſuddenly extended, ſo as to propel the trunk; for the ground effectually reſiſts the impulſe, which muſt be entirely ſpent on the moveable parts above. The alternate angles, formed by the ankles, knees, and hips, depreſs the centre of gravity, without altering its bearing on the feet; and the ſame mechaniſm enables us to elevate the trunk nearly in a vertical line, the circular motions in oppoſite directions executed with almoſt inſtantaneous velocity, acting in a ſtraight line intermediate to them all. If the flexions were all made in the ſame direction, ſubſequent extenſion would be more laborious, and a perpendicular impulſe, ſuch as produces the vertical leap, would be impoſſible. The mechaniſm of leaping may be illuſtrated by comparing it with other motions. The muſcular powers being the ſame, the leap will be more conſiderable as the levers are longer, and more inclined on each other. Hence animals, whoſe hind limbs appear diſproportionately long, can make the moſt extenſive bounds; we need ſcarcely inſtance the kangaroo, hare, ſquirrel, or graſshopper.

The elevation of the body in a vertical leap is continued ſo long as the communicated impulſe exceeds the power of gravitation; as the former diminiſhes, the latter again begins to operate, and the body deſcends in the ſame line with that in which it had been elevated. It is incapable, while in the air, of altering the general direction derived from the firſt impulſe; although many motions of the extremities may be produced, as we obſerve in dancing. The ground, from its want of elaſticity, communicates no impulſe to the body at the moment of elevation. A certain reſiſtance to the action of the muſcles on the moveable levers is required. If the ground be ſoft or ſandy, it yields too readily to the impulſe of the feet, and leaping is impeded: on the contrary, if the point from which the jumper ſprings be elaſtic, as in the caſe of a flexible board, or a tight rope, there is an evident re-action, conſiderably increaſing the impulſe communicated by the exertion of the lower limbs. In jumping forwards the trunk is inclined, and projected in the ſame direction by the extenſion of the thigh on the leg. This latter motion is counterpoiſed or varied, according to circumſtances; but it is ſo eſſential in every caſe, that we cannot leap if the knees are kept extended, no muſcular action or exertion could then raiſe the body from the ground. The chief effort is to turn the thigh and trunk balanced on it forwards on the tibia; and the impulſe thus given predominates over the others; in leaping backwards, the tibia is the more moveable diviſion of the lever by a variation in the combined action of the muſcles employed, determinable by the will. In the vertical leap the body moves up and down in the ſame line: but if the impulſe is given in a line inclined to the horizon at oblique angles, the line deſcribed by the centre of gravity will be a parabolic curve, compounded of the uniform ſtraight motion of projection, and the force of gravity, as in other projectiles. While the firſt predominates over the laſt, the body aſcends; when they are in equal power, the elevation is the greateſt; from this point, it deſcends, the force of gravity acting with increaſing effect as the impulſe is weakened. The impulſe, in this caſe, may be conſiderably increaſed by a previous motion given to the body by running: the impetus is ſomewhat altered in direction by the violent extenſion of the extremities, but it acts with almoſt undiminiſhed force in projecting the body: there are here two cauſes acting in oppoſition to gravitation. This kind of leap is facilitated by inclining the body forwards; and, in order to afford a point of ſupport to the centre of gravity, we always find, before the body is elevated from the ground, that one of the legs, generally the right, is much before the other; this poſition is preſerved throughout, for the ſame reaſon, or the two legs are brought into parallel obliquely inclined lines, before we reach the ground at the end of the leap. If we jump with the feet together, we cannot incline the body much forwards, without loſing the balance. In this caſe, to aſſiſt the impulſe, we ſwing the arms backwards and forwards before we make the ſpring, endeavouring to give ſome degree of horizontal impetus to the trunk, which muſt however always be inferior to that obtained by even a ſhort run. The body comes in contact with the ground, at the end of the leap, impreſſed by a double force, *viz.*; the projectile impetus, and that acquired by gravitation in the deſcent. We extend the feet on the legs, ſo as to touch the ground firſt by the toes; we then yield ſomewhat to the force, and allow the joints to be bent gradually, ſo as to weaken and finally deſtroy the ſhock. In order to deſtroy the impulſe given to the centre of gravity, we throw back the head and ſhoulders, and ſlacken our pace by degrees, till the power of balancing is reſtored.

The action of dancing, which conſiſts in a rapid change, in various manners and directions, of the lower extremities, principally reſembles, in ſome reſpects, the *run*, in many others the *leap*. We omit the detail of thoſe extraordinary and amazing feats of agility, which aſtoniſh us in the ſtage dancer, or the tumbler; as they depend, not on any peculiarity of mechaniſm, but on the powerful, long ſuſtained, or rapid actions of muſcles, educated to the taſk, and preſerved by conſtant exerciſe in the higheſt poſſible ſtate of energy. Hopping is a ſucceſſion of leaps on one leg only; the actions are otherwiſe analogous. Skaiting is a ſimple motion; the mechaniſm of which may be readily conceived after the obſervations we have made: the centre of gravity is brought alternately over the oppoſite feet, as each glides on the plane beneath, and the balance is preſerved by muſcular action. Swimming is a more compound action of both upper and lower extremities, involving in its diſcuſſion many intereſting queſtions, independent of their functions, and which conſequently cannot properly be conſidered here.

For more detailed information on the ſubject of animal mechanics, we refer the reader to Borelli, de Motu Animalium; Haller, Element. Phyſiol. tom. iv.; Barthéz, Nouvelle Mécanique de l'Homme: ſee Jour. des Scavans 1782-1783. Bichat, Anatomie Deſcriptive, tom. i. Cuvier, Leçons d'Anatomie compareé; tom. i. ſur la fin. There is a catalogue of authors on this ſubject in Dr. Young's Natural Philoſophy v. ii. p. 164.

Compariſon of the upper and lower extremities.—A review of the differences in the conſtruction of the upper and lower limbs will illuſtrate the mechaniſm of their component parts. There is a general reſemblance of form throughout; and the eſſential varieties may be all referred to the principle of mobility in the upper, and to that of firmneſs in the lower. In man, the extremities are nearly parallel to the long diameter of the trunk; and conſequently they muſt be parallel to each other; but they are not in the ſame vertical plane. A line drawn from the glenoid cavity of the ſcapula to the acetabulum, will be very oblique from above downwards and forwards, becauſe the plane in which the former lies is poſterior to that in which the latter is found. Hence the arm drops neceſſarily behind the thigh. The advantage of ſuch a diſpoſition in the upper extremities is, that the principal motions, which are thoſe in the anterior direction, have a greater range than if the glenoid cavity had been ſeated nearer to the front of the trunk. The extremities differ alſo in the ſpace, by which they are ſeparated from each other. If we judged only by the intervals between the right and left glenoid and cotyloid cavities reſpectively, we ſhould ſuppoſe the difference to be great; the long clavicles keeping the firſt at a greater diſtance than the pubal portions of the hip bones do the ſecond. This, however, is compenſated by the length and obliquity of the necks of the thigh bones, which throw the axes of theſe bones far without the cotyloid cavities. We have here ſuppoſed the legs to be extended, and the arms lying in their natural direction by the ſides of the trunk; if the knee and elbow be bent in this poſition, we ſhall find the angles are open in nearly oppoſite directions, that of the knee backwards, and the elbow forwards. Theſe are the only joints in which the articulations are directly inverſe in their modes of action; in quadrupeds, this condition prevails from the ſhoulder and hip to the feet in a very ſtriking manner. The lower extremities are nearer together below than above; while the upper are kept aſunder by the intervening body. The lower extremities are rather longer than the upper, in conſequence of the great length of the thigh and leg, when compared with the arm and fore arm. For the latter, by the long axis of the hand being in the ſame line with their length, gain much more than the lower extremity does by the mere thickneſs of the foot. When the arm hangs eaſily extended by the ſide, the points of the fingers reach to about the middle of the thigh; yet there are many varieties in this reſpect. The ſolid form, and the broad articular ſurfaces of the lower, are ſtrikingly contraſted with the ſlender make and narrow articulations of the upper; the firſt bearing a marked relation to their principal function of ſuſtaining the body, the latter to their diſtinguiſhing character of mobility. At the time of birth the upper extremities are more advanced in formation than the lower. This feature is, however, more remarkable, the nearer we mount to the firſt developement of the embryo; it is gradually loſt after birth, and the ſtructure of both is completed nearly about the ſame period. The different nature of their functions, thoſe of the upper commencing almoſt immediately, and thoſe of the lower not until a conſiderable interval after the birth of the child, explains eaſily the reaſon of this diſpoſition.

The bones of the hip and ſhoulder differ more in their form and connections than any other parts of the extremities. The ſcapulæ are ſuſtained by muſcles, allowing a great variety of motion, and are kept apart by the two moveable clavicles in front; the hip bones are bound firmly to the ſpine, and the articular cavities ſeparated from each other by an immoveable medium. The ſpace between the cotyloid cavities is proportionably greater in the female than in the male. The ſame exceſs may be obſerved in the ſhoulders, where it ariſes from the greater comparative length of the clavicle. The breadth of the ſcapulæ increaſes in the male the tranſverſe diameter of the ſhoulders, which on this account is particularly ſtriking from behind; in front they are not proportionably ſo wide as in the female. It is therefore the proportional exceſs of width in the hips, and not any decreaſe in the breadth of the ſhoulders, which gives to the female figure one of its moſt prominent features; this diſtinguiſhes it from the male, in whom the ſtrong, though narrow, hips are oppoſed to the comparatively ſpreading ſhoulders. Theſe circumſtances are ſufficiently evident in examining the diſpoſition of the bones; but they become ſtill more ſtriking, by the addition of the ſoft parts, in the complete ſubject, where the ſtrongly marked and muſcular form of the ſhoulders, and the contracted outline of the hips in the male, is finely contraſted with the delicacy of the firſt, and the ſwelling roundneſs of the laſt in the female. The hip bone exceeds the ſcapula and clavicle in volume, as well as in the firmneſs of its articulation; it further gives a fixed point of motion to the thigh, by a deep articular cavity, whereas the ſcapula offers a ſhallow and eaſily moveable one, yielding to a ſlight impulſe.

The femur exceeds the humerus very much in ſize, and length, (this laſt being nearly in the ratio of 46 to 33,) and in the extent of its articular ſurfaces. Although their motions are for the moſt part analogous, ſome differences may be pointed out. The movements of circumduction and rotation exiſt in an inverſe ratio to each other. In the thigh bone, the length of the neck, which is the lever of rotation, gives great extent to this motion, and thus ſupplies the want in the leg of the motions correſponding to the pronation and ſupination of the fore-arm, ſo that all rolling of the foot out and in, when the limb is extended, ariſes from a motion of the whole limb. The ſhort neck of the humerus, on the contrary, by bringing the axis of the bone nearer the centre of motion, limits rotation; which is leſs eſſential, inaſmuch as the hand is moved by the pronation and ſupination of the fore-arm. Circumduction is more confined in the thigh by this very length of the neck, which makes an angular lever of this bone, differing much from the nearly rectilineal one of the humerus. In the firſt caſe the axis of motion is not in the long axis of the bone; in the laſt, it is nearly ſo; and the difficulty of this motion is proportional to the difference between the two axes, while its facility is greater as they approach each other more nearly. The advantages of this diſpoſition, in giving mobility to the upper, and firmneſs to the lower extremities, may be readily perceived.

The leg exceeds the fore-arm in the ſize and length of the bones, the proportions being as 39 to 26. In the orang-outang the ratio of the thigh to the arm is as 9 to 10, and that of the fore-arm to the leg as 9 to 11; which proportions are very different from thoſe of the human ſubject. The exceſs of length in the lower extremity of man is ſeen moſt evidently when he attempts to move on all fours, as we expreſs it. To correct this diſproportion he is obliged to bend the joints of the lower extremities, or to throw them out very obliquely behind the trunk, whilſt the upper are perpendicular to it. The leg and fore-arm reſemble each other leſs than the thigh and arm; in the fore-arm the parts are arranged favourably to mobility; in the leg the object is to procure a firm and ſolid ſupport, which can tranſport the centre of gravity with eaſe and ſafety from one point to another. Of the two bones of the fore-arm, which are nearly equal in every reſpect, one rolls eaſily over the other, and the hand is articulated with the moveable bone. In the lower extremity theſe rolling motions would have been dangerous; to give it firmneſs, the foot is articulated with the tibia, which correſponds to the ulna, and not with the fibula; the latter poſſeſſes no perceptible power of motion.

The hand and foot reſemble each other moſt cloſely in the ſtructure and number of the phalanxes, and of the bones which ſupport them; the principal differences occur in the carpus and tarſus, which are the moſt ſolid portions. That part of the hand in which its ſtrength reſides is leſs developed, and has far leſs volume than the analogous parts of the foot, on which the whole weight of the body in ſtation finally reſts. The moveable phalanges, which are the principal agents in executing the functions of the hand, are much longer, and larger than thoſe of the toes, which are not ſo eſſential to ſtation or progreſſion. The foot and hand are diſpoſed inverſely as to form; the poſterior part of the former, and the anterior part of the latter, is the moſt important, the longeſt, and poſſeſſes the moſt ſtriking characters. The functions of the hand render it neceſſary that its plane ſhould be nearly continuous with that of the fore-arm; otherwiſe the radius could not guide it ſo preciſely over the objects in view. In the foot, the articulation is ſo diſpoſed that its poſterior part offers a powerful lever for muſcular agents, and a ſolid ſupport for the maſs above; it is formed by a ſingle bone of the foot, which neceſſarily adds to its ſolidity. The metacarpus and metatarſus have a much greater ſimilarity to each other; the latter is the more ſolid, and offers this principal difference. The metatarſal bone of the great toe, by far the ſtrongeſt of the whole, has ſcarcely any motion on the tarſus, and is on the ſame plane with the others; while that which ſupports the thumb has a very conſiderable extent of motion, and is anterior to the reſt. This ariſes from the obliquity in the articulating facet of the trapezium, which is directly tranſverſe in the firſt cuneiform bone of the tarſus. Further, this bone in the foot is not ſeparated from the other metatarſal bones, by an interoſſeous ſpace larger than that between all the reſt, as is the caſe with the metacarpal bone of the thumb. Theſe remarkable differences depend wholly on the ſolidity neceſſary for ſtation, and the great mobility required for the important offices executed by the thumb in the human ſubject. In the ape tribe, the great toe on the contrary may be properly regarded as another thumb in its ſtructure and uſes. The toes can be inflected further on the back of the foot than the fingers can be on the hand, a diſpoſition which is accommodated to progreſſion, eſpecially to running ſwiftly; an analogous effect is produced in the hand by the inflection of the carpus backwards on the fore-arm. At the time of birth the important parts of the hand are already well developed; the metacarpus, and more eſpecially the fingers, are ſufficiently formed for the infant to ſeize objects within its reach, and to diſtinguiſh ſome of their qualities. This early developement of the organs of touch would ſeem to bear a marked relation to the correſponding advancement in the formation of two other organs of ſenſe, the eye and ear, they being all aſſociated cloſely in confirming, or correcting external ſenſations. The important part of the foot, the tarſus, is far behind in formation, as it is not called into uſe till ſome time after birth, till the organs of ſenſe have long been exerciſed in common, and can now mutually aſſiſt each other.

Reſpecting this compariſon between the upper and lower limbs, ſee Vicq D'azyr ſur la comparaiſon des extremités entr'elles dans l'homme, et dans les quadrupedes, in the Hiſtoire de l'Acad. des Sciences 1774.
